SUMMARY Aortic root abnormalities (atherosclerotic thickening and obstruction) seen at necropsy may readily be detected by aortography in familial hypercholesterolaemia. We studied 35 patients with familial types IIa and IIb hyperlipoproteinaemia including three homozygotes and 32 heterozygotes. Two homozygotes showed abnormal bright echoes (atheroma) encircling the proximal aortic root, which interfered with full excursion of the aortic cusps. One homozygote showed the typical echocardiographic features of supravalvular aortic stenosis at the superior border of the sinus of Valsava with normal aortic cusps. Cardiac catheterisation showed valvular gradients of 15 and 80 mm Hg in two homozygotes and a supravalvular gradient of 40 mm Hg in the third. Left coronary artery ostial stenosis was identified by echocardiography in all three homozygotes. Echocardiographic measurements of the aortic root in the 32 heterozygotes were similar to the control group, but 10 patients showed abnormal bright echoes within the aortic cusps and four had supravalvular changes similar to, but less severe than, the homozygotes. In one severely heterozygote supravalvular atheroma prevented full aortic cusp excursion, and this finding was confirmed during coronary artery bypass surgery.

Patients with homozygous familial hypercholesterolaemia have a high mortality due to premature atheroma,1 which predominantly affects the proximal coronary arteries and aortic root.2

The aortic valve and root in homozygotes are thickened and infiltrated by atheroma. Histologically, these lesions consist of atheroma with a large number of foam cells, and they have a high cholesterol content.2 The deposition of intracellular lipid and the finding of cholesterol crystals within the aortic valve is pathognomonic for this condition and can lead to severe aortic stenosis.3 4 Aortography shows characteristic aortic root funnelling.5 Involvement of the aortic valve is considered a unique feature of the homozygote.6 An aortic systolic murmur has, however, been reported in 30% of heterozygotes.7 Pathological studies in heterozygotes showed frequent supravalvular atheroma deposition, but aortic valve involvement was found in only one of 11 patients.2

The purpose of this study was to assess the use of cross sectional echocardiography for identifying aortic root lesions and coronary artery ostial stenosis in homozygotes and to determine whether similar abnormalities were present in heterozygotes.

Patients

Thirty five patients with familial hypercholesterolaemia attending the Hammersmith Hospital lipid clinic were studied, of whom three were homozygotes and 32 were heterozygotes.

HOMOZYGOTES

Three males (aged 14, 19, and 25 years), who were all receptor defective and who have been previously described in detail5 had pretreatment serum cholesterol concentrations of 16, 18, and 22 mmol/l (618, 695, and 849 mg/100 ml) respectively. All were undergoing plasma exchange at two-weekly intervals.

HETEROZYGOTES

Thirty two patients (22 males, 10 females), with a
Cross sectional echocardiographic assessment of the aortic root and coronary ostial stenosis

mean age of 42-7±11-7 years had pretreatment serum cholesterol concentrations (mean±SD) of 8-8±2-0 mmol/l (340±77 mg/100 ml). The diagnosis of familial hypercholesterolaemia was based on serum cholesterol concentration ≥7-5 mmol/l (290 mg/100 ml) and the presence of tendon xanthomata or a history of hypercholesterolaemia with tendon xanthomata or premature myocardial infarction in a first degree relative. All heterozygotes were on a cholesterol lowering diet and many were also taking cholestyramine, nicotinic acid, or probucol.

CONTROLS
Thirty two age matched healthy normolipidaemic controls were included for comparison.

Methods
All patients underwent standard cross sectional echocardiographic study in the partial left lateral position with an ATL M1 mechanical sector scanner using parasternal and short axis views. Measurements of aortic root dimensions were made from sector guided M mode traces at end diastole, and an average measurement from five consecutive cardiac cycles was obtained. Echocardiograms were inspected for aortic root or valve abnormalities, especially cusp or wall thickening. Two sets of echocardiographic measurements were made. (1) In the three homozygotes and in one heterozygote comparisons with standard cineangiographic measurements were made by measuring the diameter of the inner aspect of the aortic root at three levels: (a) aortic annulus; (b) upper border of sinus of Valsalva; and (c) 1.5 cm above (b). (2) In all the remaining heterozygotes standard echocardiographic aortic root measurements were made in the long axis view both at the annulus and at the mid-level of the sinus of Valsalva.8

Three homozygotes and one heterozygote underwent contrast cineangiography, measurements (as described above) being made in the right anterior oblique and left lateral projections and corrected for magnification.

Angiographic and echocardiographic measurements were made by different observers. Values are quoted as mean±1 SD, and the Mann Whitney U test was used to test the differences between means.

Results
HOMOZYGOTES
Similar (within 0-3 cm) echocardiographic and angiographic measurements of aortic root dimensions were obtained in all three subjects (Table). Abnormal bright echoes could be seen encircling the aortic root, especially within the sinus of Valsalva, suggesting generalised funnelling of the supravalvular aorta. One of the homozygotes (case 1) showed a considerable reduction (47%) in the supravalvular aortic dimension at the superior border of the sinus of Valsalva when compared with the aortic diameter at the annulus without any limitation of the motion of the aortic valve cusps (Fig. 1); at cardiac catheterisation a supravalvular gradient of 40 mm Hg was noted. The other homozygotes showed moderate supravalvular narrowing (32 and 23%), but the site of haemodynamic obstruction was valvular (gradients of 15 and 80 mm Hg). In both cases a bright mass of echoes indicated atheroma in the sinus of Valsalva, which interfered with the opening of the right and non-coronary aortic valve cusps (Fig. 2). This finding was confirmed at cardiac surgery in one patient. The aortic cusps were thickened particularly in the basal portion, and both patients had a gradient at the valvular level. One homozygote also showed generalised mitral valve thickening (Fig. 2a). Serial parasternal short axis views showed extension of the abnormal aortic root with bright echoes extending into the origin of the left main coronary artery in all three homozygotes (Fig. 3).

HETEROZYGOTES
The main aortic root dimensions were 2.8±0.4 cm (annulus) and 3.1±0.5 cm (mid-sinus of Valsalva). These were similar to dimensions in normal controls (3.0±0.4 cm and 3.3±0.3 cm respectively). Ten patients had abnormal bright echoes arising from the aortic valve; in six more than one cusp was affected. The non-coronary cusp was affected in eight, and right and left coronary cusps in seven and three

heterozygotes respectively. Four had abnormal bright echoes encircling the aortic root, three of whom had mild supravalvular narrowing similar to, but less severe than, that seen in case 1. One heterozygote had a 22% reduction in the supravalvular aortic dimension (Table). All three aortic valve cusps were thickened, but their opening was restricted by the supravalvular narrowing (Fig. 4); this was confirmed at coronary artery bypass surgery, when a 15 mm valvular gradient was also found.

Discussion

Previous angiographic studies have shown characteristic aortic root funnelling, which is often associated with aortic valvular gradients, in patients with homozygous familial hypercholesterolaemia. We
Cross sectional echocardiographic assessment of the aortic root and coronary ostial stenosis

Cross sectional echocardiography offers an opportunity to study less severely affected patients in whom invasive investigations may not be justified. Of 32 heterozygotes 22 were normal, but 10 had abnormal echoes arising from the aortic valve or root. In three heterozygotes supravalvular changes similar to those in homozygotes were noted, and one had aortic valvular stenosis. This patient also had abnormal bright echoes within the sinus of Valsalva, which were associated with limitation of full excursion of the cusps. While coronary and peripheral artery stenosis may be found in both homozygotes and heterozygotes, aortic valve lesions were believed to be unique to the former. We have shown, however, that heterozygotes may have aortic valve abnormalities, root thickening, and narrowing in a similar (but usually less severe) manner to homozygotes. This is not surprising as it is possible that the serum cholesterol concentration determines the rate of deposition of lipid and overlap may occur between heterozygotes and homozygotes.

Aortic valve and root lesions consist of foam cells, cholesterol crystals, and fibrocalcific deposits. The intracellular lipid and cholesterol crystals within the aortic cusps differentiate these lesions from other causes of aortic valve disease. Similar lesions may be induced experimentally in rats fed on a high cholesterol diet. The mechanism of atheroma formation is probably an increased influx of low density lipoprotein in areas of high sheer stress, such as the sinotubular junction and aortic and mitral valves. The tricuspid and pulmonary valve are not affected, perhaps because they are not submitted to such great sheer stress.

Cholesterol concentrations in homozygotes may vary widely depending on the available number of cellular receptors. These range from 0 to 10% of the normal number of low density lipoprotein receptors, which probably explains the wide age range of morbidity and mortality in homozygous familial hypercholesterolaemia. Myocardial infarction can occur as early as 18 months of age, but survival beyond the age of 30 has also been reported. Most homozygotes, however, die before the age of 25.

The left main coronary artery may be identified by cross sectional echocardiography, and stenosis has been shown in some patients. Our homozygote patients were young, but we found left coronary ostial stenosis in all three; right coronary ostial stenosis was not recognised in one homozygote, however, in whom it was shown by coronary angiography.

In conclusion, cross sectional echocardiography may show valvular or supravalvular obstruction and coronary ostial stenosis in patients with homozygous familial hypercholesterolaemia. In addition, heterozygotes may show similar aortic root and valve

have shown that echocardiography and angiography give comparable results and that a wide spectrum of abnormalities may be seen. Abnormal bright echoes arising from the aortic root and valve were often noted, and in two homozygotes and one heterozygote supravalvular atheroma prevented full aortic valve opening and was responsible for the valvular gradients. Supravalvular narrowing was clearly seen in one homozygote by cross sectional echocardiography and confirmed by the presence of a supravalvular pressure gradient. Only one previous case of pronounced supravalvular aortic stenosis has been described in a homozygote. A considerable reduction in aortic lumen has to be present before a gradient develops, and premature coronary artery disease dominates the clinical picture. In two of our homozygotes the mechanism of valvular stenosis was secondary to supravalvular atheroma preventing normal cusp motion. Classic hourglass supravalvular aortic stenosis with echocardiographically normal cusps was also shown. In addition, one homozygote showed generalised mitral valve thickening. This can lead to haemodynamically important stenosis if calcification occurs.
abnormalities, although these are usually less severe. Serial cross sectional echocardiographic studies may well prove useful for monitoring the progress of the disease and the effect of treatment such as plasma exchange.
