Chronotropic incompetence: a proposal for definition and diagnosis

Demosthenes Katritsis, A John Camm

Between 1958 and 1960 Astrand documented the normal heart rate response to exercise in healthy individuals and noted that the maximum heart rate decreased with age.1,2 A reduced cardiac chronotropic response to isoprenaline has been reported in elderly subjects and alterations in catecholamine-adrenergic receptor interactions may be responsible for this change of cardiovascular regulation in the elderly.3-5 In addition the parasympathetic innervation of the sinus node is currently under investigation.6 Over the years it has also been recognised that an inadequate chronotropic response (chronotropic incompetence) at maximal exercise is common in patients with cardiovascular disease7,8 and much interest has centred on the pathophysiological mechanism(s) involved in chronotropic incompetence.9,10 Despite this, no universally accepted definition of chronotropic incompetence exists and the criteria for its diagnosis are not defined. However, a precise diagnosis of this condition is of clinical importance. First, adaptive-rate pacing may be beneficial in patients who clearly demonstrate chronotropic incompetence.11-14 Secondly, chronotropic incompetence has also been documented in patients with chronic heart failure and may contribute to the impairment of physical capacity seen in these patients.7,15

Terminology and definitions
The term chronotropic incompetence implies the inability of the heart to increase its rate in proportion to metabolic demand. Consequently, it refers either to inadequacy of the sinus node or, in the case of complete heart block, of the lower escape pacemaker to respond to exercise or other autonomic changes. Unfortunately in published reports a clear distinction is not always made between chronotropic incompetence of the sinus node and of the lower escape pacemaker.

The current definitions of chronotropic incompetence usually rely on the heart rate response achieved at maximal exercise. The expression which was formulated by Astrand to predict the age dependent maximum sinus rate response to exercise (maximum predicted heart rate, MPH) was MPH = (220-age) beats/min and chronotropic incompetence has been arbitrarily defined as a maximum exercise heart rate achieved during exercise testing that is <75% or <80% of the predicted MPH. Other arbitrary definitions such as a maximum exercise heart rate <100 beats/min or <120 beats/min have also been used. However, the achievement of maximum exercise is not always possible. Elderly cardiac patients, especially those disabled by chronotropic incompetence, are unable to perform sufficient exercise on the treadmill. Furthermore, everyday life activities of these patients usually correspond to low work loads up to 6 metabolic equivalents corresponding to the first stage of the standard Bruce protocol. In addition, not much is known about the patterns of heart rate acceleration and deceleration in the presence of chronotropic incompetence.

Wilkoff et al.16 using exercise testing with respiratory gas analysis and employing a less demanding protocol, the so-called Chronotropic Assessment Exercise Protocol (CAEP), recently established a method by which the chronotropic response during submaximal exercise can be assessed. This was achieved by comparing relative metabolic levels with relative heart rates—that is, by normalising the change in heart rate from rest to maximal exertion as a linear function of the change in metabolic workload. The normal predicted heart rate at some submaximal stage of exercise, regardless of the protocol used, is given by the formula:

\[ \text{HR}_{\text{age}} = \left( \frac{220-\text{age}-\text{HR}_{\text{rest}}}{\text{METS}_{\text{peak}}-1} \right) \times \left( \frac{\text{METS}_{\text{peak}}-1}{\text{METS}_{\text{peak}}} \right) + \text{HR}_{\text{rest}} \]

where METS = \( \frac{\text{VO}_{2} (\text{ml/kg/min})}{3.5} \), and \( \text{METS}_{\text{peak}} = \) the peak functional capacity achieved during the test.

This formula is proposed as a guide to the expected heart rate at various stages of exercise in normal subjects able to exercise to maximum workload, but it gives no idea as to the expectation in patients who are unable to achieve anaerobic peak exercise. In these patients the application of the formula will produce an exaggerated estimate of chronotropic incompetence during submaximal exercise because of its reliance on \( \text{METS}_{\text{peak}} \) as a denominator in the equation. Wilkoff’s methodology has been recently used by Kay17 in a proposed model for assessment of the pacing rates offered by adaptive-rate pacemakers from the beginning of exercise to complete recovery.
Chronicotropic incompetence: a proposal for definition and diagnosis

Prevalence
The prevalence of this condition in most patient populations is not known and the inconsistency in defining chronicotropic incompetence in the various reported studies makes comparative analysis of the existing data difficult. It has been suggested that approximately 40% of the pacemaker population exhibit some degree of chronicotropic incompetence and might benefit from rate-adaptive pacing and that this percentage increases with time after implantation. The prevalence of chronicotropic incompetence in sick sinus syndrome (due to inadequate response of the sinus node), defined as <120 beats/min at maximum exercise, has been reported to range from 28% to 57%. Characteristically, the definition of chronicotropic incompetence in the published series is not always clear. In atrial fibrillation (usually due to inadequate response of the atrioventricular node conduction) the chronicotropic response to exercise may be impaired in up to 60% of the patients. In patients with acquired complete heart block (usually due to inadequate response of the His-Purkinje pacemaker) chronicotropic incompetence is almost universal. Chronicotropic incompetence is not only important in patients with primary conduction disease but is also common in patients with heart failure whether this is caused by ischaemic heart disease or dilated or hypertrophic cardiomyopathy. Studies are currently underway to determine the true prevalence of chronicotropic incompetence in such patients and to assess whether the restoration of chronicotropic competence is of therapeutic benefit.

Proposals
Definitions
A standard definition of chronicotropic incompetence is proposed based on an anatomical and a physiological differentiation. From an anatomical perspective chronicotropic incompetence is divided into sinus nodal, junctional, or ventricular. Whereas from a physiological perspective we have proposed a distinction between two varieties: specific or functional.

Chronicotropic incompetence is the inability of the heart rate to achieve at least 80% (an arbitrary percentage for the time being) of the predicted value according to Astrand's formula (220− age) at peak exercise—that is, achievement of the anaerobic threshold. Inability of the heart rate to achieve at least 80% of the predicted value according to Wilkoff's formula at any stage of submaximal exercise may also denote a form of chronicotropic incompetence that at present is particularly relevant to the pacing rate modulation offered by adaptive-rate pacemakers.

Sinus node chronicotropic incompetence is the inability of the sinus node to achieve at least 80% of the predicted rate. Specific sinus node chronicotropic incompetence is the inability of the sinus node to accelerate in response to metabolic demands secondary to intrinsic disease or negative chronicotropic drugs. Functional chronicotropic incompetence manifests itself either as atrial tachyarrhythmias or as retrograde ventriculo-atrial conduction resulting in sinus node reset, pacemaker-mediated tachycardia, or the so-called atrioventricular desynchronisation arrhythmia (that is, unsensed retrograde P waves followed by ineffectual atrial stimulation during atrial refractoriness). In such cases there is interference with sinus node activity preventing an appropriate sinus node rate response to exercise or autonomic changes.

Functional chronicotropic incompetence in patients with permanent atrial fibrillation implies inability of the heart rate to achieve 80% of the predicted values owing to the atrioventricular conduction defect. Also in patients with complete heart block it refers to the inability of the escape junctional pacemaker to achieve at least 80% of the predicted value. In cases of an infra-hisian or infra-hisian block the term ventricular chronicotropic incompetence is more appropriate—to denote incompetence of the escape focus.

Diagnosis
Ideally, cardiopulmonary exercise testing with respiratory gas analysis is required for a proper assessment of the chronicotropic response, though this facility is not universally available. We propose the following practical scheme:

1. If patients achieve more than 80% of their predicted maximum heart rate during an ordinary exercise test chronicotropic incompetence is not present.
2. In patients unable to achieve at least 80% of their predicted maximum heart rate on exercise, exercise testing with respiratory gas analysis should be performed, particularly in patients with abnormal left ventricular function.

(a) Patients who achieve the anaerobic threshold are chronotropically incompetent.

(b) In those patients who do not reach the anaerobic threshold at peak exercise, submaximal chronicotropic incompetence at any stage of submaximal exercise can be assessed according to Wilkoff's formula. Since the "METS" value available will be necessarily smaller than the one that corresponds to the anaerobic threshold, chronicotropic incompetence can be excluded if the heart rate response is higher than 80% of that predicted according to the formula. If the achieved heart rate response is less than 80% of that predicted, chronicotropic incompetence cannot be excluded.
