Two unusual complications after surgical interruption of an accessory pathway

Emile C Cheriex, Joep L R M Smeets, Hein J J Wellens

Abstract
In a patient with the Wolff-Parkinson-White syndrome, Ebstein’s anomaly of the tricuspid valve, a right atrial Chiari net and a patent foramen ovale, two unusual complications developed after surgical epicardial dissection combined with cryoablation of the anomalous pathway.

The first complication was that ablation of the right atrial wall led to changes in interatrial pressure gradients and the development of a right to left shunt necessitating surgical closure of the atrial septal defect. The second complication was the development of a thrombotic mass in the Chiari net simulating an intracavity tumour, which also had to be removed surgically.

(Br Heart J 1993;70:471-473)

Two unusual complications occurred after surgery for the Wolff-Parkinson-White syndrome in a patient with Ebstein’s anomaly of the tricuspid valve with a patent oval foramen who had recurrent circus movement tachycardia through a right-sided accessory atroventricular pathway.

Case report
A 19 year old man was examined in 1981 because of Wolff-Parkinson-White syndrome and circus movement tachycardia. Echocardiography showed Ebstein’s anomaly of the tricuspid valve. The septal leaflet was attached 3 cm apical to the attachment of the mitral valve, so that the ratio of the atrialised part of the right ventricle to the ventricular part of right ventricle was 1:1. Echocardiography also showed an aneurysm of the interatrial septum, indicating patency of the foramen ovale. A Chiari network was clearly present in the right atrium. An electrophysiological study proved the presence of a right lateral accessory atroventricular connection.

During catheterisation it was possible to cross the foramen ovale. Oximetry showed no shunt at the atrial level (saturations: superior vena cava 76%, inferior vena cava 82%, right atrium 77%, pulmonary artery 77%, pulmonary veins and left atrium 97% and left ventricle 96%). The patient’s exercise tolerance was normal and no cyanosis was noticed during exercise.

In January 1989 poorly controlled tachycardia prompted epicardial dissection combined with cryoablation of his accessory connection without the use of extracorporeal circulation. Postoperatively the patient had significant systemic arterial undersaturation, believed to be caused by central shunting.

A transoesophageal echocardiogram showed a freely moving flap valve of the foramen ovale and contrast echocardiography showed right to left shunting. The right lateral part of the right atrium above the annulus fibrosis appeared completely akinetic for almost 3 cm. The shunting was thought to be mainly the result of a change in pressure gradient between right and left atrium. Right-sided catheterisation was performed during mechanical ventilation. The mean right atrial pressure was 14 mm Hg and mean left atrial pressure was 7 mm Hg.

The oxygen saturations were as follows: superior vena cava 51%, inferior vena cava 53%, right atrium 50%, pulmonary artery 53%, pulmonary veins 98%, left atrium 47–95% depending upon the sampling site, and left ventricle and aorta 85%. These values indicated considerable right to left shunting in a patient whose general condition was deteriorating. The patient was operated on and the atrial defect was closed successfully.

Recovery was uneventful and an echocardiographic investigation one week after the second operation showed no signs of shunting or other additional abnormalities. At routine follow up six months later echocardiography showed a large partially mobile tumour in the right atrium. Because this tumour seemed to be connected to the Chiari network a venous thrombus entrapped in the Chiari network was diagnosed (figs 1 and 2). After three weeks treatment with intravenous heparin the tumour did not decrease in size. Indium-III labelling of platelets did not show any activity in the right atrium and venous system, suggesting absence of active thrombus formation. Reoperation was performed and the thrombus was removed together with the Chiari network. The postoperative course was uneventful and the patient is currently symptom free.

Comment
Ebstein’s anomaly of the tricuspid valve is an uncommon congenital abnormality, characterised by apical displacement of the septal leaflet of the structurally abnormal tricuspid valve into the right ventricle without displacement of the annulus fibrosis. Wolff-Parkinson-White syndrome is reported to occur in 5–25% of patients with Ebstein’s disease. An atrial septal defect or patent foramen ovale was reported in 60–80%. Right to left shunting through the defect causes variable degrees of cyanosis in 60–80% of...
patients. Right ventricular failure, tricuspid incompetence, and increasing right atrial pressure are the main reasons for right to left shunting. The patient presented here is exceptional. To our knowledge an abrupt change in inter-atrial flow, from absence of any clinical shunting to severe symptomatic right to left shunting has not been reported before. In this patient cryosurgical trauma to the right atrium, causing akinesia of a considerable part could have influenced the inter-atrial pressure gradient. The second unusual complication in this patient was the entrapment of a venous thrombus in the Chiari network. Entrapment prevented pulmonary embolism.

Echocardiographically detected right-sided heart thrombi are uncommon. The reported mortality associated with these echocardiographically detected thrombi is 29–100%. Most thrombi visualised in the right heart are parts of a larger thrombus that is still partly "fixed" in the inferior vena cava. We know of no other descriptions of thrombi entrapped in the Chiari network. Two case reports, however, describe paradoxical embolisation and pulmonary emboli in patients with Ebstein's anomaly. In one the thrombus was detected echocardiographically before death. Survival mainly depends on the prevention of pulmonary emboli. The calculated probability of survival without treatment in this patient was 50% according to the logistic regression calculation of Kinney and White. After three weeks of unsuccessful heparinisation the thrombus was removed surgically. We do not know why venous thrombosis developed in this patient. The Chiari network prevented the thrombus from causing pulmonary embolism. Paradoxical embolisation was not a possibility because the atrial septal defect had been closed.

SHORT CASES IN CARDIOLOGY

Primary hyperparathyroidism presenting as torsades de pointes

Peter Kearney, Michael Reardon, James O'Hare

A previously well 47 year old woman presented to hospital complaining of syncopal episodes over the preceding 24 hours and of anorexia, nausea, polyuria, polydipsia, and generalised aches and pains for 2 weeks. She lost consciousness and her electrocardiograph showed short runs of multiform ventricular tachycardia (figure). These worsened, degenerating into ventricular fibrillation that required repeated DC cardioversion. The arrhythmia was refractory to intravenous lignocaine, magnesium, and amiodarone and stabilised only after a transvenous pacemaker set to 100 beats/min was inserted. Clinical examination was unremarkable. Serum biochemistry showed hypokalaemia (3-1 mmol/l) and hypercalcaemia (3-12 mmol/l). Twenty-four hour urinary calcium was increased (13-5 mmol) and a parathormone assay (INTACT IRMA) showed a concentration of 517 pg/ml (normal range 5-15 pg/ml) that confirmed the diagnosis of primary hyperparathyroidism. A parathyroid adenoma weighing 2-79 g was found and excised and the patient made an uneventful recovery.

Hypokalaemia, a well recognised precipitant of torsades de pointes1 is noted in approximately 5% of cases of primary hyperparathyroidism.2 It is probably a result of proximal (type II) and, to a lesser extent, type I renal tubular acidosis. Secondary hyperaldosteronism resulting from intravascular volume depletion can also occur.

Hypercalcaemia also may have contributed. The increases in heart rate and contractility caused by parathormone are thought to be the result of direct induction of calcium influx into myocardial cells and the release of endogenous myocardial adrenaline.3 Hypercalcaemia shortens the plateau phase of the action potential, leading to a shorter QT interval. Re-entry is one proposed electrophysiological mechanism underscoring torsades de pointes and in this context the positive chronotropic and QT-shortening effect of parathormone might be expected to protect against the arrhythmia by decreasing intraventricular dispersion of refractoriness. Calcium administration reduced the propensity to ventricular fibrillation by shortening the QT interval in dogs.4

There is, however, also evidence that an increased calcium concentration might have an arrhythmogenic effect by enhancing early afterdepolarisations, which have more recently been hypothesised to underlie torsades de pointes.5
