LETTERS TO THE EDITOR

The British Heart Journal welcomes letters commenting on papers that it has published within the past six months.

All letters must be typed with double spacing and signed by all authors.

No letter should be more than 600 words.

In general, no letter should contain more than six references (also typed with double spacing).

Asymptomatic ischaemia during daily life in stable coronary artery disease: relevant or redundant

Sir,—In their interesting review on the prognostic implications of silent myocardial ischaemia, Mulcahy et al, referring to our paper on silent ischaemia after myocardial infarction, wrote: "Solimene et al performed ambulatory ST segment monitoring in 40 patients eight weeks after a first myocardial infarction and followed them for two years. Six patients had asymptomatic ischaemia during ambulatory monitoring. No events occurred in them: there was one cardiac death in a patient without ischaemia." There was some misinterpretation of our data. In fact, our investigation showed that 11 (27·5%) out of 40 patients had silent ischaemia after infarction: five only on exercise testing, five on exercise testing and Holter monitoring, and one on Holter monitoring. Of those 11 patients, four (36%) had a non-fatal cardiac event whereas only one (3·6%) of 29 patients without silent ischaemia had a cardiac event (fetal reinfarction) during this two year follow up. Kaplan-Meier analysis showed that during this period patients without silent ischaemia had much less likely to experience a cardiac event (5·5%) than patients with ischaemia (62·3%) (P < 0·007). We concluded that silent myocardial ischaemia after myocardial infarction is of considerable prognostic significance—a somewhat different conclusion from that reached by Mulcahy et al.

This letter was shown to the authors, who reply as follows:

SIR—I thank Dr Solimene for her letter. Our review was about the prognostic significance of transient myocardial ischaemia detected on ambulatory ST segment monitoring and not exercise testing or any other form of investigation. In her letter Solimene confirms the figure noted in six patients with transient ischaemia on ambulatory monitoring after myocardial infarction. In their study of 40 patients Solimene et al related silent ischaemia after myocardial infarction during daily life to any investigation (that is, exercise testing, n = 10; ambulatory monitoring, n = 6; one or the other, n = 11) to events, and not to a straight assessment of ambulatory ischaemia as such outcome. Only one "hard" coronary event (acute myocardial infarction or sudden coronary death) was reported by Solimene et al (cardiac death), and this occurred in a patient who did not have transient ischaemia on ST segment monitoring. We reported this in our review which focused on the relation between transient ischaemia and subsequent death or non-fatal myocardial infarction. Recurrence of angina (referred to as a non-fatard cardiac event by Solimene et al) was reported to occur in four patients with silent ischaemia during exercise testing or ambulatory monitoring—Solimene et al do not state which. To reply to Solimene's letter in the context of our review, and to establish whether "soft" end points occurred in those with transient ischaemia during daily life, we would need to know how many of these four recurrences of angina occurred in those with only a positive exercise test and whether anything further happened to them.

Issues in cardiac pacing: can age be justified?

SIR,—The continuing debate surrounding the cost-effectiveness of rate adaptive pacing in the elderly remains handicapped by a lack of reliable data.1 The antagonists would point to the absence of hard clinical evidence to support the use of sophisticated pacemaker technology in the elderly. Recent trials, however, which specifically included elderly subjects, have confirmed the clinical impression that the elderly stand to gain as much from physiological pacing as younger patients.2,3 However, the biggest stick with which to beat the enthusiasts is that of cost. In a retrospective analysis, de Belder et al estimated that implantation of dual chamber pacemakers in all suitable patients (that is, those with advanced atrioventricular block and sinus rhythm) aged over 75 years would have added an extra £264 357 to the regional pacing budget (an increase of 57%).4 Quoted if figures it is little wonder that there is some reluctance to implement the BPEG guidelines in the elderly.5 It is important to realise, however, that these figures were based on the assumption that all electrophysiologically suitable patients aged over 75 would have been given DDD pacemakers.

Patients aged over 75 years may constitute a selected group in whom the presence of advanced conduction disease may be a marker of an advanced aging process. Limiting, non-cardiac disease or cognitive impairment (for example, previous stroke)—is not uncommon in this group and such patients would not normally be considered for a dual chamber system. We do not know how many of our patients are offered VVI systems on the grounds of limiting, non-cardiac disease or cognitive impairment. Nevertheless, it is clear that available estimates of the financial implications of the BPEG guidelines are likely to be exaggerated and serve only to foster inappropriate implantation policies.

In addition to further clinical trials, which are likely to confirm the overall benefits of physiological pacing in the elderly, we need reliable information on the costs of implementing these research findings.

Detection of left ventricular dysfunction after myocardial infarction: comparison of clinical, echocardiographic, and neurohormonal methods

SIR,—A major limitation of the Peet index, even in its modified form1 is that it does not take into account the adverse prognostic significance of the association of a done-early blood pressure and ST segment depression. In thrombolytic trials such patients continue to have a high mortality despite treatment,2 not only because ST segment depression is an independent predictor of poor prognosis3 but also because it sometimes signifies structural damage caused by previous myocardial infarction.4 Furthermore, even when patients with ST segment depression prove to have smaller infarcts than their counterparts with ST segment elevation,5 they still have more severe impairment of left ventricular systolic function.6 These patients should, therefore,
