Can clonidine, enoximone, and enalaprilat help to protect the myocardium against ischaemia in cardiac surgery?

Joachim Boldt, Gabriele Rothe, Ehrenfried Schindler, Carsten Döll, Gerold Görlich, Gunter Hempelmann

Abstract

Objective—to evaluate whether clonidine, enoximone, and enalaprilat reduce ischaemia-related myocardial cell damage in cardiac surgery.

Design—Prospective randomised controlled trial.

Setting—Clinical investigation in a cardiac anaesthesia department of a university hospital.

Patients—88 consecutive patients undergoing coronary artery bypass surgery.

Interventions—After induction of anaesthesia patients continuously received the α₂ agonist clonidine (group 1, n = 22), the phosphodiesterase (PDE) III inhibitor enoximone (group 2, n = 22), the angiotensin converting enzyme (ACE) inhibitor enalaprilat (group 3, n = 22), or saline solution as placebo (control group, n = 22). The infusion was stopped immediately before the start of cardiopulmonary bypass.

Main outcome measures—The ST segment was analysed and the activity of creatine kinase isoenzyme MB (CKMB), cardiac troponin T (TnT), and the BB isoenzyme of glycogen phosphorylase (GPBB) were measured before the start of infusion (baseline), after weaning from cardiopulmonary bypass (CPB), at the end of surgery, 5 h after CPB, and on the morning of the first and third postoperative days.

Results—Biometric data and time of cross-clamping were not significantly different in the four groups. Changes in the ST segment indicating ischaemia were least common in the enalaprilat group (P < 0·05). Postoperatively, CKMB activity was significantly higher in the clonidine and the control groups. Both new markers of myocardial cell damage increased more after CPB and postoperatively in the control patients (TnT peak: mean (SD)) 3·99 (0·35) μg/l; GPBB peak: 82 (15) ng/ml) and the clonidine-treated group (TnT peak: 3·80 (0·3) μg/l; GPBB peak: 85 (14) ng/ml). Enalaprilat-treated patients showed the smallest overall changes in standard (CKMB) and new serological markers of myocardial ischaemia (TnT peak: 0·71 (0·1) μg/l; GPBB peak: 44 (14) ng/ml).

Conclusions—in patients treated with enalaprilat before CPB, both new, more sensitive markers of ischaemic myocardial tissue damage increased significantly less than in an untreated control group. Those treated with enoximone also had lower plasma concentration of TnT and GPBB than the control group, whereas clonidine did not reduce the concentration of these markers of myocardial ischaemia. Pharmacological interventions, such as the continuous infusion of the ACE inhibitor enalaprilat, before start of CPB may help to protect the heart against ischaemia/reperfusion injury.

Keywords: ischaemic markers, myocardial preservation, myocardial tissue damage, surgery.

Patients undergoing coronary artery bypass grafting (CABG) are at risk of myocardial cell injury. Detection of ischaemia in these patients is difficult. Standard indices such as electrocardiogram or creatine kinase MB were not sensitive and specific enough to detect minor ischaemia-related myocardial tissue damage. Standard laboratory variables, such as the activity of the creatine kinase isoenzyme MB (CKMB), have been shown to be a serological marker for more extensive ischaemic myocardial cell injury. CKMB release from skeletal muscle after surgery, however, can also increase plasma CKMB.

In recent years, new markers of myocardial ischaemia have been used to assess the degree of myocardial tissue damage. Cardiac troponin T (TnT) is 100% cardiосpecific. TnT was demonstrated to be more sensitive to and specific for myocardial tissue damage secondary to angina or infarction than commonly used serological markers of ischaemia. Therefore, TnT was found to have a sensitivity of 98% and a specificity of 98% or even 100%. By contrast, the sensitivity of CKMB was found to be only 84% and specificity was 98%. Thus TnT is believed to be superior to CKMB activity in the diagnosis of minor myocardial cell damage.

The isoenzyme BB of glycogen phosphorylase (GPBB) is another promising method for detecting ischaemic myocardial cell damage more precisely. Glycogen phosphorylase is the key enzyme of glycogenolysis. There are three major isoenzymes of GP: one is detected in the brain (BB) and is also found in human myocardium, a second is detected in muscle (MM), and a third is found in the liver (LL). GPBB in the myocardium is associated with glycogen and the sarcoplastic reticulum.
This macromolecular complex (sarcoplasmic reticulum-glycogenolysis complex) is broken down during ischaemia and GPBB is released into the sarcoplasm. Myocardial ischaemia results in glycogenolysis and (transient) alterations in plasma membrane integrity. During myocardial ischaemia GPBB is released into the circulation from (ischemically) injured myocardial tissue. This increase in circulating GPBB seems to peak earlier than standard (CKMB) or newer (for example, TnT) markers of myocardial damage.

Several pharmacological approaches have been used to reduce the incidence of perioperative myocardial ischaemia in cardiac surgery. Less ischaemia and/or improved myocardial function have been reported after treatment with glyceryl trinitrate, the Ca++ channel blocker nifedipine, and acadesine. Promising results were also reported with the centrally acting α-adrenoceptor agonist clonidine, the phosphodiesterase (PDE)-III inhibitor enoximone, and angiotensin converting enzyme (ACE) inhibitors (for example, enalaprilat). Most studies, however, were based on monitoring the electrophysiology and systemic haemodynamics or were carried out in an experimental setting. Data on the cardioprotective effects of clonidine, enalaprilat, and enoximone during cardiac surgery have not yet been evaluated precisely. Thus the present study was designed to investigate whether intraoperative treatment with these drugs reduced ischaemia-related myocardial cell damage in patients undergoing coronary artery surgery.

Patients and methods

STUDY GROUPS

We studied 88 patients undergoing elective first time coronary artery bypass grafting (CABG). The study was approved by the ethics study committee and informed consent was obtained from all patients. Exclusion criteria were renal insufficiency (serum creatinine >1.5 mg/dl), unstable angina, left ventricular ejection fraction (LVEF) <40%, left ventricular end diastolic pressure (LVDPD) >25 mm Hg, and a mean arterial blood pressure (MAP) <70 mm Hg in a haemodynamically steady state after induction of anaesthesia. Except for aspirin, preoperative medication was continued until the morning of the operation (table 1).

Preoperatively, the patients were allocated randomly to continuous intravenous infusion of one of the following: group 1 (n=22) clonidine (0.05 μg·kg·min⁻¹); group 2 (n=22) enoximone (5 μg·kg·min⁻¹); group 3 (n = 22) enalaprilat (0.6 μg·kg⁻¹·min⁻¹); group 4 (n = 22) saline solution given as placebo (control patients). The infusion was started after induction of anaesthesia and was continued until the start of CPB.

Postoperatively, filling pressures (PCWP, central venous pressure (CVP)) were maintained between 12 and 15 mm Hg by infusion of PRBC (when haemoglobin was less than 9 g/dl) or Ringer’s solution and low molecular weight (LMW) hydroxyethyl starch (HES) solution. To guarantee adequate haemodynamic function (MAP > 60 mm Hg, CI > 2.25 l min-1 * m-2), systemic vascular resistance (SVR) > 700 dyn·s·cm-5) during weaning from CPB and in the post-CPB period adrenacline, dobutamine, and norepinephrine were given where necessary. Glyceril trinitrate or nifedipine were given when ST-segment analysis indicated ischaemia or filling pressures (PCWP, CVP) were > 15 mm Hg. All patients’ lungs were mechanically ventilated for at least 5 h after CPB (PaO2 was kept between 100 and 150 torr (3-3 and 20-0 kPa) and PaCO2 between 38 and 45 torr (5-0 and 6-0 kPa)).

MEASURED VARIABLES AND DATA POINTS

MAP and heart rate (HR) were measured continuously. Additionally, all patients were monitored by means of a pulmonary artery catheter.

ST segment changes were analysed serially (Sirecust 1280, Siemens, Erlangen, Germany). Records of leads II and V5 were analysed by physicians who were blinded to the grouping of the patients. Ischaemia was defined as horizontal or down-sloping ST segment of at least 0-1 mV, which extended at least 80 ms beyond the J point of the QRS complex, and/or as an elevation of > 0-2 mV at the J point lasting for at least 1 min.20 Myocardial infarction was defined by electrocardiographic (ECG) strip chart (occurrence of new Q waves or a deepened Q wave of one-third of the QRS height and > 0.04 s) and increasing CKMB activity (normal < 12 U/l). ECG strip charts were always interpreted by physicians who were blinded to the grouping of the patients.

Activities of creatine kinase isoenzyme MB (CKMB) (Boehringer Mannheim, Germany) measured with a Hitachi 717 analyser (normal value < 12 U/l), plasma concentration of cardiac troponin T (TnT) measured with a commercial monoclonal-monoclonal, double antibody, one step sandwich enzyme immuno-assay (ELISA) (Boehringer Mannheim); normal value < 0.1 µg/l, and the isoenzyme BB of the glycogen phosphorylase (GPBB) measured with a commercial, standardised enzyme-linked immunosorbent assay for the determination of human GPBB using two murine monoclonal antibodies21 (Laboserv, Giessen, Germany) (normal value: none detected or < 5 ng/ml). were measured in central venous blood samples. All measurements were carried out before start of infusion (baseline values), after weaning off CPB, at the end of surgery, 5 h after CPB, and on the first and third postoperative days. We used the following formula to correct the volume for all markers of ischaemia22:

\[
\text{correction factor: phc}_\text{t} = \frac{\text{phc}_t}{\text{hct}^\text{a}}
\]

where phc = plasma haematocrit (100% - hct%), to = value at baseline, and ti = value at the time of sampling.

STATISTICAL ANALYSIS

All variables are expressed as mean (SD). Demographic data and outcome data (for example, number of patients who needed inotropic support) were tested using the chi-

group-time interaction for each measured variable. $P$ values $< 0.05$ were regarded as statistically significant.

Results

The groups did not differ with regard to demographic and intraoperative data (table 1). The test drug was given for 70 min to 95 min, with no significant differences in duration between the groups. Two of the clonidine (9%) and two of the control patients (9%) had myocardial infarction (diagnosed from the ECG and an increase in CKMB activity). Pacing was necessary significantly more often in the clonidine group (n = 9) than in the other patients (table 1). More patients in the clonidine group than in the other pre-treated groups needed inotropic support (adrenaline, dobutamine) and vasodilators (glyceryl trinitrate) after being taken off the bypass ($P < 0.05$) (table 2). Similar numbers of patients in the clonidine and the control groups had ST-segment changes (table 3). ST segment changes were least common in the enalaprilat-treated patients ($P < 0.01$). All patients were transferred to a normal ward by the second day and none of the patients died during the study period. All patients were doing well (stable haemodynamics, no ECG changes) when they were discharged from hospital.

Infusion of all three substances produced similar reductions in MAP (table 4). HR decreased in the clonidine group (from 69 (5.3) to 60.4 (7.9) min$^{-1}$), whereas HR in the other groups remained almost unchanged during the infusion period (table 4). CI was reduced only in the clonidine patients (from 2.78 (0.2) to 2.39 (0.2) l min$^{-1}$m$^{-2}$) and increased in the enoximone patients (from 2.51 (0.3) to 3.19 (0.3) l min$^{-1}$m$^{-2}$) ($P < 0.05$) (table 4).

CKMB activity was similar in all four groups before and after CPB as well as at the end of surgery and 5 h after CPB (fig 1). On the first postoperative day, CKMB was significantly higher in the clonidine (35.1 (4.9) U/l) and the control group (34.2 (5.8) U/l) than in the enoximone (17.1 (3.1) U/l) and enalaprilat patients (7.5 (2.3) U/l, $P < 0.001$).

Baseline values of plasma TnT were normal in all the groups ($< 0.1$ jg/l); there were significant differences between the groups after CPB (fig 2). At the end of surgery, TnT had increased most in the clonidine (from 0.01 (0.04) to 0.99 (0.2) jg/l) and the control groups (from 0.01 (0.01) to 1.01 (0.18) jg/l). In the group pretreated with clonidine, plasma TnT concentration increased significantly in the postoperative period, with a peak increase of 3.80 (0.3) jg/l on the first postoperative day. In the control patients, it increased significantly from baseline values to 3.99 (0.35) jg/l. In the groups treated with enoximone and enalaprilat, TnT increased only slightly (enoximone from 0.01 (0.01) jg/l to a peak of 1.19 (0.1) jg/l; with the enalaprilat group showing the lowest increase (from 0.01 (0.010) jg/l to a peak of 0.71 (0.1) jg/l).

Can clonidine, enoximone, and enalaprilat help to protect the myocardium against ischaemia in cardiac surgery?

P < 0.001) compared with the other groups.

Starting from comparable baseline values (< 1 ng/ml), GPBB plasma concentrations after CPB did not differ among the treated patients (fig 3). In the enalaprilat group they remained significantly lower during the entire postbypass and postoperative period (peak 44 (13) ng/ml at the end of surgery) than in the other groups (P < 0.01). Plasma concentrations of GPBB were similar in the clonidine-treated patients (peak 85 (14) ng/ml 5 h after CPB) and the control group (peak 82 (15) ng/ml).

Discussion

Several substances have been claimed to have anti-ischaemic effects in patients undergoing cardiac surgery.15-17 The beneficial action of the centrally acting α₂ adrenoceptor agonist clonidine was attributed to a reduction in sympathomimetic outflow. In an experimental setting, clonidine was shown to be of benefit in avoiding myocardial ischaemia.24 In patients undergoing CABG, oral pretreatment with clonidine (5 μg/kg) reduced the incidence of ischaemic ST segment changes compared with an untreated control group.17 Clonidine did not provide the myocardium of our patients with much protection from ischaemia: ST segment alterations indicating ischaemia were most often seen in these patients and CKMB plasma concentrations increased after CPB, which was taken to indicate myocardial issue damage.25 Serial measurements of two more sensitive markers of myocardial cell damage, TnT and GPBB, were similar in the clonidine and control groups. The increases in TnT plasma concentrations of our control (and clonidine) patients in the postbypass and postoperative periods were similar to those reported by Mair et al who found an increase of up to 3.5 U/l in patients with an "uncomplicated" course after CPB and of more than 3.5 U/l in patients showing ischaemically induced TnT-segment changes.18 Hofmann et al reported on three patients undergoing CABG and found a plasma concentration of GPBB of about 50 ng/ml after release of the cross-clamp (that is, the beginning of reperfusion),19 which accords with the data of our clonidine, control, and enoximone groups in the postbypass period.

The PDE-III inhibitor enoximone may influence myocardial ischaemia either by its (direct) effects on the cAMP system or (indirectly) by improving coronary (micro) perfusion. In patients in whom ventricular pacing was performed, enoximone increased the angina threshold while the left ventricular stroke work index was maintained.20 The question whether this effect was due only to reduction in wall stress secondary to vascular vasodilatation, was studied by Schlepper et al.21 Intracoronary administration of enoximone (0-075 mg/kg) into a stenosed coronary vascular bed produced no noticeable systemic haemodynamic effects, serum concentrations were below therapeutic concentration but anti-ischaemic effects were still seen. In our study, both new markers of minor myocardial cell damage were less increased in the enoximone group than in the untreated control group after CPB and later in the postoperative period, which seems to indicate less postbypass myocardial cell damage. These beneficial effects of enoximone may also result from its endocrinological consequences (for example, decrease in plasma vasopressin and decrease in plasma and myocardial catecholamines).22

The renin angiotensin system (RAS) seems to play an important part in cardiovascular homeostasis23 and the benefit of interruption of the RAS by ACE inhibitors during perioperative stress has already been demonstrated.24 Protective effects of ACE inhibitors after myocardial infarction have been convincingly demonstrated.25 In patients with myocardial ischaemia showing abnormal myocardial lactate metabolism, enalaprilat relieved myocardial ischaemia.26 ACE inhibitors also had cardioprotective effects when they were given before ischaemia. In an experimental setting when myocardial ischaemia was induced by coronary occlusion, enalapril resulted in a preservation of myocardial tissue.19 When intravenous enalaprilat was given to our patients in the pre-bypass period it significantly reduced ischaemia-related sequelae in the myocardium. ST segment changes were least common and changes in both new markers of (minor) myocardial cell injury (TnT, GPBB) were smallest during the entire postbypass and postoperative period in the group treated with enalaprilat. The mechanisms of the beneficial effects of ACE inhibitors in this situation has not yet been clarified. ACE inhibitors act not only by blocking systemic angiotensin converting enzyme but also by inhibiting tissue ACE.27 Stimulation of prosta-
cyclin synthesis, increased endothelial production of nitric oxide, and limitation of endothelin production may also contribute to their cardioprotective effects.28 The beneficial effects of ACE inhibitors in our study contrast with results in an experimental setting.29 When various ACE inhibitors were given 10 min before a 25 min period of global ischaemia and during a 30 min period of reperfusion in the isolated rat heart, an improvement in post-ischaemic contractile function and a reduction in cell death was seen only in the groups that had captopril and zofenopril-sulphhydril added; enalaprilat was not cardioprotective in high concentrations. The authors assumed that only sulphhydril-containing ACE inhibitors (not enalaprilat) are effective in limiting ischaemic myocardial tissue damage.

One major problem is that the optimal doses for myocardial protection of the infused substances are not definitely known. We gave 0.05 μg·kg⁻¹·min⁻¹ of clonidine continuously by intravenous infusion, a total dose of 307 (26) μg. In trying to reduce ischaemic and reperfusion-related stress, Kulk et al used 2 to 6 μg/kg intravenously,30 which is comparable to the dosage in our study. Others used oral clonidine (for example, 5 μg/kg 90 min before surgery31), which gives widely varying plasma concentrations. Our dose of enoximone was
also commonly given by others and does not appear to have detrimental haemodynamic effects. Doses of single bolus injection of enalaprilat vary widely, from 0.625 mg to 40 mg. Doses of 0.2 mg to 1.2 mg in patients with myocardial infarction almost completely suppressed plasma angiotensin enzyme activity.

Although all the drugs used in this study have long pharmacological half lives, we gave them by continuous intravenous administration because this route is associated with fewer negative haemodynamic sequelae. Data from the present study do not show whether different plasma concentrations of the three drugs at the end of the ischaemic period (in the reperfusion period after release of aortic cross-clamp) influenced myocardial cell damage. Because almost all of them have a half-life greater than 60 min, all seem to be present in the reperfusion period and thus may have influenced post-CABG myocardial ischaemia in this way as well.

It is difficult to compare the results of our study with those of other studies focusing on myocardial ischaemia in cardiac surgery patients because of the widely varying study conditions. Different methods of myocardial preservation (for example, different cardioplegic solutions), different patient populations (for example, valve versus CAGB patients, stable versus unstable angina), different degrees of hypothermia, varying periods of aortic cross-clamping, and different technique of anaesthesia may influence the degree of ischaemia-related myocardial cell damage.

It was not the aim of the present study to determine whether drugs can help to improve outcome in cardiac surgery. This would require comprehensive multicentre studies. However, the importance of intraoperative ischaemia in these patients has recently been emphasised. According to Mangano et al the positive predictive value of intraoperative ischaemia was better than that of postoperative ischaemia (33% vs 26%) as was the specificity (79% vs 64%)—that is intraoperative ischaemia may indicate a higher risk than postoperative ischaemia. The present study was performed in elective coronary artery bypass grafting. The beneficial cardioprotective effects may be of particular interest in emergency or complicated surgical procedures with expected prolonged ischaemic periods and patients at higher risk of myocardial ischaemia.

In summary, one major therapeutic aim in cardiac surgery should certainly be the prevention of myocardial ischaemia. New markers of myocardial ischaemia such as cardiac troponin (TnT) and the isoencyme BB of the glycerol phosphorylase (GPBB) give us a better way of monitoring our attacks at cardioprotection. Intravenous enalaprilat given in the pre-ischaemic period resulted in the smallest overall increase in these markers of ischaemia after CPB, whereas clonidine had no beneficial cardioprotective effects and cannot be recommended for this purpose in cardiac surgery. Our results should prompt further investigations in reducing myocardial ischaemia in cardiac surgery patients.

Can clonidine, enoximone, and enalaprilat help to protect the myocardium against ischaemia in cardiac surgery?

A 63 year old woman presented with tiredness and ankle swelling and was found to have systemic venous congestion. Her anterior-posterior and lateral (A) chest x rays showed a rim of calcification mainly affecting the inferior part of the pericardium and the diagnosis of calcific constrictive pericarditis was subsequently made. Her condition gradually worsened despite treatment with diuretics, and surgery was considered. A preoperative spiral computed tomograph (B) with a 3D reconstruction shows that the pericardial calcification is more extensive than suggested by the x rays. Calcification involved the pulmonary arteries and the whole of the inferior and posterior parts of the pericardium. This information is helpful to the surgeons in their approaches to pericardiectomy.
