LETTERS TO THE EDITOR

Scope
Heart welcomes letters commenting on papers published in the journal in the previous six months. Topics not related to papers published earlier in the journal may be returned as a letter; letters reporting original data may be sent for peer review.

Presentation
Letters should be:
- not more than 600 words and six references in length
- typed in double spacing (fax copies and paper copy only)
- signed by all authors.

They may contain short tables or a small figure. Please send a copy of your letter on disk. Full instructions to authors appear in the July 1996 issue of Heart (page 93).

Evaluation of mortality and morbidity during four years after late thrombolysis in acute myocardial infarction
Sir,—The effect of late coronary reperfusion after acute myocardial infarction (AMI) remains contentious. Coronary angiography is the gold standard for determining vessel patency; however, routine early catheterisation after thrombolytic therapy is not practicable for most patients with AMI. Continuous ST segment monitoring and imaging with 99mTc-labelled Sestamibi are useful markers of successful reperfusion and coronary artery patency after thrombolysis. In a preliminary study we found lower 3 year mortality in 87 AMI patients thrombolysed within 20 hours than in 65 AMI patients treated with heparin alone.1

In present study to determine whether late patency of the infarct-related artery affects the mortality and morbidity in AMI, we studied 228 patients (150 males and 78 females, aged 57 (5) years) treated with alteplase (rt-PA) (group 1: n = 155) or heparin (group 2: n = 73). Patients were eligible if they were <70 and their duration of pain was >3 h (from 6-20 h after onset of symptoms). The efficacy of rt-PA thrombolysis, in terms of patency achieved, was assessed by non-invasive clinical criteria: continuous ST segment monitoring, early MB-CK peak (<20 h), imaging with 99mTc-Sestamibi, sudden decrease in chest pain, and serial changes in abnormal wall motion. Four-year mortality was 6-5% in rt-PA patients (group 1) and 14-6% in those given heparin alone (group 2 n = 73, P < 0-01).

Is thrombolytic therapy really better than conventional treatment in acute inferior myocardial infarction?
Sir,—Without wishing to prolong the debate on the relative benefits of thrombolytic therapy for patients presenting with inferior myocardial infarctions, we would like to make a correction of fact to Dr Tobe's reply to our letter in the British Heart Journal (1995;74:476-478). The Fibrinolytic Therapy Trialists (FTT) overview clearly reports that 39% of patients (which we rounded up to 40%) of those forming the group who may be eligible to receive thrombolytic therapy are patients with ST elevation inferiorly, and not the 28% of patients to which Dr Tobe has been limited (16 203) n is 39% of the potentially thrombolytic eligible group (total 41 765).

Readers can consider the correspondence on the interpretation of the data as presented by ourselves and Dr Tobe and come to their own conclusions on the appropriateness of thrombolytic therapy in patients presenting with inferior ST elevation who represent 40% of patients who are potentially eligible on the basis of the FTT overview.
