The increased ventilatory response to exercise in chronic heart failure: relation to pulmonary pathology

Andrew L Clark, Maurizio Volterrani, Jonathan W Swan, Andrew J S Coats

Abstract
Objective—To assess the exercise limitation of patients with chronic heart failure (CHF) and its relation to possible pulmonary and ventilatory abnormalities.

Setting—A tertiary referral centre for cardiology.

Methods—The metabolic gas exchange responses to maximum incremental treadmill exercise were assessed in 55 patients with CHF (mean (SD) age 57·9 (13·0) years; 5 female, 50 male) and 24 controls (age 53·0 (11·1) years; 4 female, 20 male). Ventilatory response was calculated as the slope of the relation between ventilation and carbon dioxide production (VE/\(\text{VCO}_2\) slope).

Results—Oxygen consumption (\(\text{VO}_2\)) was the same at each stage in each group. Ventilation (\(\text{VE}\)) was higher in patients at each stage. Patients had a lower peak \(\text{VO}_2\) and a steeper \(\text{VE/}\text{VCO}_2\) slope than controls. Dead space ventilation as a fraction of tidal volume (\(\text{VD/VT}\)) was higher in patients at peak exercise, but dead space per breath was greater in controls at peak exercise \((0·74 (0·29) v 0·57 (0·17) \text{litres/breath}; P < 0·002)\). End tidal \(\text{CO}_2\) was lower in patients at all stages, and correlated with peak \(\text{VO}_2\) \(r = 0·58, P < 0·001\). Alveolar oxygen tension was higher in patients at each stage than in controls.

Conclusions—Patients with CHF have an increased ventilatory response at all stages of exercise. Although this is accompanied by an increase in \(\text{VD/VT}\), there is hyperventilation relative to blood gases. It is more likely that the excessive ventilation is not due to a primary pulmonary pathology, but rather, the increase in dead space is likely to be a response to increased ventilation.

(Heart 1997;77:138–146)

Keywords: metabolic gas exchange; dead space ventilation; chronic heart failure; exercise

The cardinal feature of the syndrome of chronic heart failure is exercise limitation. The symptoms causing limitation are most frequently shortness of breath and muscle fatigue. Either symptom can occur in the same patient depending upon the type of exercise undertaken. The syndrome is commonly assessed clinically using incremental exercise protocols to determine ventilation and metabolic gas exchange. Peak exercise capacity is measured as peak oxygen consumption (\(\text{VO}_2\)), although the reduction in peak \(\text{VO}_2\) characteristic of chronic heart failure correlates only poorly with indices of haemodynamic function. Many investigators have shown that there is an increase in ventilation, and this increase in ventilation (\(\text{VE}\)) expressed as an increase relative to the rate of carbon dioxide production (\(\text{VCO}_2\)), as \(\text{VE/}\text{VCO}_2\) slope, correlates closely with reduction in peak \(\text{VO}_2\).

To account for the increased ventilatory response, several investigators have proposed that dead space ventilation is increased, although how this abnormality is sensed is difficult to imagine, given the stability of arterial blood gas tensions during exercise in heart failure. We have explored the relations between ventilation, blood gas tensions, dead space, and metabolic gas exchange in a large group of patients with chronic heart failure and age matched controls in an attempt to determine the cause of the ventilatory abnormalities.

Methods
We examined the responses of 55 patients (average age 57·9 (SD 13·0) years; five female, 50 male) with documented treated, stable chronic heart failure. The diagnosis was confirmed by the presence of at least the following: (1) evidence of impaired left ventricular function from radionuclide scanning, cross sectional echocardiography, or cardiac catheterisation; and (2) a cardiothoracic ratio of greater than 0·5, a left ventricular ejection fraction of less than 0·45, abnormal left ventricular chamber dimensions, or raised end diastolic pressure. Exercise tests were undertaken as part of their routine assessment. No patient had any intercurrent illness. Patients with a past history of lung disease, or who were current smokers, were excluded from analysis. All patients had been clinically stable and on stable medication for at least three months before exercise testing, and all patients were limited by either fatigue or shortness of breath on exercise. No patient had peripheral or pulmonary oedema. No patient was stopped by angina or claudication. Details of diagnosis and medication are given in table 1. The average forced expiratory volume in one second (FEV₁) was 96·7% of the expected and the forced vital capacity (FVC) was 93·5% of expected. No patient with results less than 75% of expected was included in this study.
Twenty four control subjects were recruited from patients attending for routine medical examinations (four female, 20 male). No subject was a current smoker, or gave any history of past cardiorespiratory disease. None was taking intermittent medication. Average age was 53.0 (11.1) years. Fully informed signed consent was obtained from each subject, and all procedures had been approved by the local ethics committee.

The exercise protocol used was a standard Bruce treadmill protocol modified by the addition of a "stage 0" at the onset of exercise—that is three minutes of exercise at 1 mile per hour with a 5% gradient. Subjects were encouraged to exercise to exhaustion. Subjects breathed through a one way valve connected to a mass spectrometer (Amis 2000; Odense, Denmark) allowing expired air to be collected; metabolic gas exchange and ventilation were determined on line every 10 seconds by a standard inert gas dilution technique. A second mass spectrometer inlet allowed end tidal carbon dioxide and oxygen tensions to be measured. Respiratory rate was counted from the capnograph.

Data were taken after a minimum of three minutes resting while the subject was attached to the apparatus. Resting readings were only taken when the reading for ventilation was stable over at least 30 seconds. At the end of each stage, and at peak exercise, the data for the last three readings were averaged to give a single reading. Fractional dead space was calculated from the alveolar ventilation equation:

$$V_E = V_{CO2} \times 863/PaCO2 \times (1 - VD/VT)$$

where $V_E$ is minute ventilation, $VD/VT$ describes dead space ventilation as a proportion of tidal ventilation, $PaCO2$ is the arterial partial pressure of carbon dioxide, and 863 is a constant to standardise gas measurements to body temperature, pressure and saturation. End tidal carbon dioxide tension was assumed to equate with arterial carbon dioxide tension, and was calculated as:

$$Pa(gas) = (F_{ET}(gas)/100 \times (BP - 47)/7.5)$$

where $Pa(gas)$ is the arterial partial pressure of a gas, $F_{ET}(gas)$ is the fractional concentration of end tidal gas, BP is barometric pressure (mm Hg), 47 is the partial pressure of water vapour, and 7.5 converts from mm Hg to kPa. Alveolar oxygen tension was calculated in a similar manner.

Absolute dead space ventilation (ADV) was calculated from:

$$ADV = V_E \times (VD/VT)$$

and dead space per breath (DS/Br) was calculated from:

$$DS/Br = ADV/respiratory rate$$

With the exception of the peak exercise measurements, these derived variables were only calculated at the end of each three minute stage to allow steady state gas exchange to be present.

Unpaired t tests were used to compare patient and control groups. The heart failure group was divided into two groups on the basis of severity of heart failure (see below). As there was drop out of the more severely affected heart failure patients between stages 1 and 2, statistical analysis of the effects of diagnostic group and exercise performance was restricted to resting, stage 1, and peak exercise. To establish trends across the controls and patient groups during exercise, a repeated measures analysis of variance was used, with severity of heart failure as a factor and stage of exercise as a repeated measures factor, corrected for multiple comparisons with Scheffe’s procedure. Linear regression by the least squares method was used to determine correlations between variables. Results are quoted as means (SD), or where a paired t test comparison is made as mean (SEM). Corrected P values of less than 0.05 were taken to be significant.

### Results

#### EXERCISE VARIABLES

Table 2 shows the overall results obtained during exercise. As expected, the peak $V_{O2}$ was greater ($P < 0.001$) in the controls than in the patients with heart failure, and exercise time was greater ($P < 0.001$). The $V_{E}/V_{CO2}$ slope was steeper in the patient group ($P < 0.001$), but the respiratory exchange ratio (RER) at peak exercise was similar in each group. RER was greater than 1 in all cases, indicating that at least near maximal exercise had been reached.

In the patient group there was an inverse relation between peak $V_{O2}$ and $V_{E}/V_{CO2}$ as previously reported, but this was not seen among the normal subjects. The relation was best described by a semi-log curve ($V_{E}/V_{CO2}$ slope $= 70.55 - 29.19 \times \log V_{O2}$, $r = 0.65$, $P < 0.001$) (fig 1).

**METABOLIC GAS EXCHANGE**

There was no significant difference between the groups in $V_{O2}$ and $V_{CO2}$ at the end of each stage of exercise, as would be expected given the similar external work loads. Thus resting

Results are shown for the comparison between end of stage 1 and peak exercise. \( \text{Paco}_2 \) is calculated arterial carbon dioxide tension, and \( \text{Pco}_2 \) is arterial oxygen tension. Values are in kPa.

\( P \) values refer to paired \( t \) tests comparisons between peak and stage 1 values; hence values in this table are means (SEM).

\( \text{VO}_2 \) was 5.10 (1.31) ml/kg/min in the patients and 5.15 (1.53) in the controls; and 14.79 (2.89) at the end of stage 1 in the patients and 16.43 (3.50) in controls.

There was, however, dropout of subjects between stages, particularly marked in the heart failure group, as subjects reached their maximum tolerated exercise level—from 55 patients at rest, only 41 reached the end of stage 1.

\( y = 70.55 - 29.19 \times \log(x) \)

\( r = 0.65, P < 0.001 \)

Figure 2  Plots of measured arterial blood gases and values for arterial carbon dioxide and alveolar oxygen partial pressures calculated from end tidal fractions. The lines are the lines of identity.

EFFECTS OF SEVERITY OF HEART FAILURE

In order to assess the effects of severity of heart failure, the patients were divided into two groups on the basis of their peak \( \text{VO}_2 \); group 1, mild heart failure and group 2, severe heart failure. A division at 17 ml/kg/min was chosen to allow comparison of similar numbers of patients. The breakdown of patients is shown in table 3. There were no significant differences between the two patient groups in indices of metabolic gas exchange at each stage.

After stage 1, the numbers of patients in the severely affected group fell off so as not to allow further comparisons at matched workloads.

RESPIRATORY GASES

The end tidal \( \text{CO}_2 \) for patients at each stage was: rest, 5.14 (0.73)%; stage 1, 5.47 (0.93); stage 2, 5.66 (0.73); stage 3, 5.79 (0.60); and peak exercise 4.98 (1.06). For the control group, end tidal \( \text{CO}_2 \) was: rest, 5.54 (0.46)%; stage 1, 6.27 (0.53); stage 2, 6.38 (0.61); stage 3, 6.31 (0.66) and peak exercise, 5.94 (0.60).

End tidal oxygen in patients was: rest, 15.17 (0.97)%; stage 1, 15.28 (1.15); stage 2, 15.45 (0.93); stage 3, 15.54 (0.36); and peak exercise, 16.31 (1.17). For the control group, end tidal oxygen was: rest, 14.44 (0.76)%; stage 1, 13.91 (0.67); stage 2, 14.24 (0.80); stage 3, 14.82 (0.84); and peak exercise, 15.66 (0.71).
In order to assess the possible effects of heart failure on the calculations of arterial carbon dioxide and alveolar oxygen tensions from end tidal fractional concentrations, and thus to ensure that the data from end tidal fractional gas concentrations were valid, we measured arterial blood gas tensions in 10 patients at rest and at peak exercise. The measured arterial carbon dioxide tension was the same as calculated arterial carbon dioxide tension: 4.67 (0.20) kPa v 4.95 (0.26) at rest; 4.75 (0.20) v 4.79 (0.22) at peak exercise. The mean (SD) of the differences between measured and calculated arterial PaCO₂ was -0.16 (0.30). The arterial oxygen tension was non-significantly lower than the calculated alveolar tension at rest (13.89 (0.60) v 14.81 (0.58); NS), achieving significance at peak exercise (14.50 (0.60) v 15.44 (0.60); P = 0.004) (fig 2). The mean (SD) of the differences between arterial and alveolar (end tidal) O₂ was -0.93 (0.47). Thus arterial carbon dioxide tension calculated from end tidal fraction is, as expected from the diffusion characteristics of carbon dioxide, an accurate reflection of arterial carbon dioxide. The alveolar oxygen tension calculated from end tidal oxygen fraction, however, significantly overestimates the arterial oxygen tension. This is consistent with an alveolar-arterial oxygen difference in the order of 1 kPa (fig 2).

Figure 3 A–D shows the behaviour of the calculated arterial carbon dioxide tension and alveolar oxygen tension (PaO₂) across the three groups: controls, mild heart failure, and severe heart failure. Note that at each comparison, the patient groups have a higher PaO₂ and a lower PaCO₂. The differences within each group from stage 1 to peak exercise are shown in table 4; the carbon dioxide tension falls and the oxygen tension rises in each group.

VENTILATION
There was no difference between the three groups in ventilation at rest: 12.5 (3.5) l/min in the controls, 14.7 (4.0) in the mild heart failure group, and 14.6 (3.9) in the severe heart failure group. At the end of stage 1 exercise, ventilation was greater in patients than in controls, and greater in the more severely affected patients: controls 32.4 (10.5) l/min; mild heart failure (n = 28) 35.9 (9.3); severe heart failure (n = 14) 44.1 (13.2); P < 0.001.
Clark, Volterrani, Swan

for trend. At the end of further stages of exercise, ventilation was similar in all groups: stage 2: controls 44-5 (15-6); mild heart failure (n = 21) 48-3 (13-1); severe heart failure (n = 5) 54-8 (11-9); P = 0.004 for trend; stage 3: controls (n = 21) 60-4 (16-2); mild heart failure (n = 11) 59-1 (14-6): NS. This reflects the fact that the later stages of exercise consist of comparisons between controls and patients with mild heart failure, as the more severely affected patients had already stopped exercise. However, at peak exercise ventilation was significantly greater in the controls than in the patients: controls 87-4 (27-4); mild heart failure 64-3 (20-3), severe heart failure 48-5 (13-3): P < 0.001 for trend. This suggests that ventilation itself was not a limiting feature and that ventilation reflected exercise load.

The respiratory pattern appeared to be altered in that patients had smaller tidal volumes and higher respiratory rates than controls at matched work loads (fig 4 A and B and table 5 A–C). However, at peak exercise, respiratory rate was similar in all groups, while tidal volume was significantly greater in the control group, at 2-9 (0-9) v 2-0 (0-6) litres: P < 0.001. Dead space as a fraction of tidal volume (VD/VT) was greater in patients at stage I and at peak exercise (fig 5A), but minute dead space ventilation (litres/min) was greater in patients only at stage 1 (fig 5B). At peak exercise, minute dead space ventilation was greater in the control group, reflecting the greater peak expired ventilation. Dead space per breath was greater in controls at stage 3 and at peak exercise: stage 3: 0-65 (0-20) v 0-43 (0-16) litres/breath: P = 0.004; peak exercise: 0-74 (0-29) v 0-57 (0-17): P = 0.002; fig 5C. This presumably reflects the greater tidal volume in controls and hence higher absolute values for dead space per breath despite a higher dead space as a fraction of tidal volume in the patient group.

CORRELATES OF EXERCISE PERFORMANCE
As expected, in the patient group, there were strong correlations between peak VO2 and exercise time (r = 0-87, P < 0.001), VCO2 (r = 0-79, P < 0.001), and ventilation at peak exercise (r = 0-57, P < 0.001). These correlations reflect the fact that as exercise duration increases, so inevitably do indices of ventilation and metabolic gas exchange. More interestingly, there was a good correlation between peak VO2 and PaCO2 at peak exercise (r = 0-58, P < 0.001) (fig 6), suggesting that the inability to exercise in more severe heart failure is associated with hyperventilation relative to arterial carbon dioxide. There was no correlation with PaO2. Of the indices of dead space ventilation, there was a negative correlation between peak VO2 and peak VD/VT (r = –0-45, P < 0.001) but no correlations with either absolute dead space ventilation or dead space per breath (fig 7 A–C).

PREDICTORS OF EXERCISE PERFORMANCE
We wished to explore possible predictors of exercise capacity, that is, which resting variables, or variables from early in exercise,

The increased ventilatory response to exercise in chronic heart failure: relation to pulmonary pathology

**Discussion**

Most previous experiments designed to assess the effects of chronic heart failure on ventilation during exercise, and the possibility of ventilatory abnormalities being determinants of exercise capacity in heart failure, have been conducted using cycle ergometry. Ventilation has been shown to be increased in heart failure. The ventilatory response relative to carbon dioxide production appears to be related to the severity of heart failure, and it has been suggested by reference to the alveolar ventilation equation that the increase in ventilation is due to an increase in dead space ventilation. The ventilatory pattern in some experiments has been found to be abnormal in heart failure, with an increased respiratory rate at lower tidal volumes for a given minute ventilation, which may lead to an increase in the anatomical dead space ventilation.

Fewer experiments have been performed using treadmill exercise. Treadmill exercise is more often stopped by breathlessness than fatigue, and is a more reliable method for determining a plateau of oxygen consumption (Vo2 max). Even in fit subjects, bicycle exercise elicits a lower peak Vo2 than treadmill exercise, as well as in heart failure, as a smaller muscle mass is used. Experiments using treadmill exercise have found that anatomical dead space is unlikely to be an important contributor to the increased ventilatory response, and other studies have drawn attention to the possible contribution of pulmonary abnormalities, in particular FEV1, and FVC. We undertook an investigation of venti-

\[ FEV_1 \] (as a percentage of the expected normal value to correct for body size) correlated with peak Vo2 (r = 0.52, P = 0.004), with peak VE (r = 0.60, P < 0.001), and with peak dead space per breath (r = 0.55, P = 0.003). There was a weak negative correlation with peak VD/VT (r = -0.49, P = 0.008). Similarly, percentage FVC correlated with peak Vo2 (r = 0.52, P = 0.004), with ventilation at peak exercise (r = 0.73, P < 0.001), and with peak dead space per breath (r = 0.62, P < 0.001). There was again a weak negative correlation with peak VD/VT (r = -0.47, P = 0.01). There were no significant correlations between these spirometric variables and the Vd/Vco2 slope. We used indices of ventilation at the end of stage 1 to attempt to predict eventual exercise performance. There was a correlation between peak Vo2 and the following stage 1 variables: VE (r = -0.47; P < 0.001), VD/VT (r = -0.38; P = 0.005), and minute dead space ventilation (r = -0.56, P < 0.001). The potentially predictive variables were then entered into a stepwise multiple regression model. After the effects of the percentage FEV1 were accounted for (r = 0.72, P < 0.001) only the Vd/Vco2 slope was independently correlated with peak Vo2, thereby increasing the overall correlation to 0.85, accounting for approximately 70% of the variation in peak Vo2.

**Figure 5** Ventilatory indices during exercise. Vd/VT is dead space as a fraction of tidal volume. Absolute dead space is minute dead space ventilation (Vd/VT × Vt) and dead space per breath is absolute dead space × respiratory rate. P values as for fig 3.
lation and metabolic gas exchange in a large group of heart failure patients during treadmill exercise in order to explore possible determinants of exercise tolerance in this setting.

METABOLIC GAS EXCHANGE
We have shown a reduced peak VO$_2$ in chronic heart failure, in common with other investigators, and a negative correlation between peak VO$_2$ and the VE/VCO$_2$ slope. The level of ventilation during the early stages of exercise is greater in the patient group, although during the later stages—after the more severely affected patients have "dropped out"—the levels of ventilation are similar in the two groups. The VO$_2$ at any stage during exercise is similar in both patients and controls, as the exercise load is the same. We have also found that during exercise, the arterial CO$_2$ tension is lower in patients than in controls at any given stage, and that CO$_2$ tension at peak exercise correlates with peak VO$_2$. We have also shown that the alveolar oxygen tension is higher at each stage in the patients than controls.

RESPIRATION
As other investigators have shown that with bicycle exercise$^{10}$ the respiratory pattern is altered in patients. At each stage, the respiratory rate is greater and the tidal volume smaller in patients with heart failure. At peak exercise, however, the respiratory rate is the same, with tidal volume greater in the control subjects, consistent with the greater total ventilatory response seen in this group (fig 4 A and B), albeit at a higher total workload.

Dead space was examined in three ways. Fractional dead space ventilation, as Vd/VT—that is, dead space as a fraction of tidal volume—was greater in the patients during early

stages, and at peak exercise. However, when dead space was interpreted as minute (or absolute) dead space ventilation—that is, total dead space ventilation per minute—it was higher in the patients early in exercise, but was greater in controls at peak exercise. This latter finding is consistent with the higher peak minute ventilation seen in the control group. We found dead space per breath to be the same in both groups early in exercise, but to be greater in the control group at peak exercise. This is a reflection of the fact that the increase in ventilation at peak exercise was proportionately greater in normal controls than the increase in dead space fraction in heart failure patients.

An increase in dead space per breath in patients relative to controls has previously been reported by Sullivan et al., and increased dead space has been widely accepted as a major contributing factor to the increased ventilatory response to exercise. However, this study rests on observations made in 18 patients and eight controls, using cycle exercise. The results from both the present study and Sullivan’s are similar for the group with heart failure. However, in Sullivan’s control group, Vd/VT fell at peak exercise to approximately 0.15. We estimate that the contribution of anatomical dead space alone in Sullivan’s controls was in excess of 0.1, and it may be that the peak Vd/VT was underestimated in Sullivan’s control group.

CONTROL OF VENTILATION

If a primary respiratory abnormality is responsible for the abnormal ventilatory response in heart failure, as has been suggested, then there should be some signal generated by the respiratory abnormality resulting in an increased ventilatory drive. The signal would be expected to be an abnormality of arterial blood gas tensions. In this study, at equivalent stages, patients and controls have the same levels of metabolic gas exchange, yet ventilation is greater and arterial carbon dioxide tensions are lower in patients at each stage, suggesting that hyperventilation is occurring with respect to arterial gases. Similarly, alveolar oxygen tension is greater in patients than controls. Although alveolar oxygen is not the same as arterial oxygen tension, we and others have previously shown that the alveolar/arterial oxygen difference is unchanged in chronic heart failure, and in that case it seems likely that hyperventilation is taking place relative to arterial oxygen tension as well. In the current study, we have also seen that the lower the peak Vo2, the lower the arterial CO2 at peak exercise.

Previous investigators have also shown a small fall in arterial CO2 and a rise in arterial O2 during exercise. Herrlin and Sylven have shown an increase in arterial oxygen content—and Hachamovitch et al a decrease in arterial CO2 content—in heart failure consistent with our findings. This is the opposite of what would be expected if a respiratory abnormality were the cause of the increase in ventilation. The present findings suggest that the more limited patients are with heart failure, the more they hyperventilate and reduce arterial CO2, and that the increased ventilatory response of heart failure probably has an alternative stimulus. Exercise is not, therefore, limited by an impairment in pulmonary function.

It is difficult to envisage how an abnormality such as dead space per breath, or dead space fraction (Vd/VT), could arise as a primary abnormality or indeed be sensed by the body. The observed abnormalities of ventilation—the increase in respiratory rate, lower tidal volumes, and lower ventilation at peak exercise—could be a response to an abnormal stimulus: the increase in dead space fraction could be a response to, rather than a cause of, excessive ventilation; a response seen as one which prevents arterial carbon dioxide tension from falling too low. Exercise is likely to be limited by something other than ventilatory abnormalities, as further suggested by the much lower peak ventilation seen in the patient group.

EXERCISE LIMITATION

Why do patients with heart failure experience exercise limitation? In this experiment, we found correlations between FEV, and FVC and peak Vo2, as seen by others. This may suggest that airway flow is a limiting feature, but again, no change in blood gases is seen. Many of the variables are compound variables: FEV, for example, is a reflection not only of airway function but of respiratory muscle strength. Much recent work has drawn attention to the abnormalities of skeletal and respiratory muscle in heart failure. The possibility exists that there is an underlying abnormality of skeletal muscle resulting in both the sensation of muscle fatigue and an excessive ventilatory stimulus. The ventilatory abnormalities in chronic heart failure could, therefore, be secondary to changes elsewhere in the body, and in particular in skeletal muscle.

LIMITATIONS TO THE PRESENT STUDY

We only measured arterial blood gas tensions in a minority of patients and used the end tidal CO2 as an estimate of arterial CO2. While this appears justified on the basis of blood gas analysis in a subset of our patients, this may not have been representative of the group as a whole. Indeed, it might be expected that as Vd/VT becomes greater any difference between arterial and end tidal CO2 would increase, although the difference was small in a group of anaesthetised subjects.

We cannot completely exclude a role for an increase in dead space ventilation during exercise in chronic heart failure. However, if this were a major pathophysiological mechanism, it would require a greatly increased ventilatory response to a change in arterial CO2 too small to detected.
