Effects of coronary revascularisation on myocardial blood flow and coronary vasodilator reserve in hibernating myocardium

D Pagano, F Fath-Ordoubadi, K J Beatt, J N Townend, R S Bonser, P G Camici

Abstract

Objective—Previous studies have suggested that resting myocardial blood flow is within normal limits in most chronically dysfunctional left ventricular segments which improve function after coronary artery revascularisation (hibernating myocardium). The aim of this study was to assess myocardial blood flow and coronary vasodilator reserve in hibernating myocardium before and after coronary revascularisation.

Patients and methods—30 patients with multivessel coronary disease undergoing coronary revascularisation (21 patients with bypass grafting and nine with coronary angioplasty), and 21 age and sex matched healthy volunteers (controls). Myocardial blood flow (MBF, ml/min/g) was measured by positron emission tomography using oxygen-15 water at rest and after dipyridamole (MBFdip, 0.56 mg/kg in four minutes). Coronary vasodilator reserve was calculated as MBFdip/MBF. Regional wall motion was assessed with echocardiography.

Results—Before revascularisation there were 48 remote and 275 dysfunctional myocardial segments, of which 163 (59%) improved function after revascularisation (hibernating). In hibernating segments coronary vasodilator reserve before revascularisation was significantly lower than in remote segments (1.97 (0.7), p < 0.0001) and controls (3.2 (1.5), p < 0.0001). In hibernating segments, myocardial blood flow remained unchanged after revascularisation (0.94 (0.3) v 0.95 (0.3) ml/min/g, p = 0.3) while coronary vasodilator reserve increased (1.47 (0.7) v 1.98 (1.0), p < 0.0001). Myocardial blood flow was similar in remote, hibernating segments before and after revascularisation and in controls.

Conclusions—This study confirms that myocardial blood flow at rest in hibernating myocardium is within normal limits in most segments, and that hibernating myocardium is characterised by an impaired coronary vasodilator reserve which improves significantly after coronary revascularisation.

Methods

STUDY POPULATION

The patient population consisted of 30 subjects (28 males; mean (SD) age 56 (10) years) with coronary artery disease (> 6 months) undergoing coronary artery bypass grafting (CABG, 21 patients) or percutaneous transluminal coronary angioplasty (PTCA, nine patients). All patients were in sinus rhythm and had suffered at least one (range 1–3) Q wave myocardial infarction 30 (14) months before the study. Seven patients were diabetic and five were hypertensive. The left ventricular ejection fraction (LVEF) was 30 (11)%. Patients were receiving treatment with angiotensin converting enzyme (ACE) inhibitors (20 patients), diuretics (15 patients), digoxin (5 patients), nitrates (10 patients), calcium channel blockers (13 patients), and β blockers (9 patients). All medical treatment was withdrawn at least 24 hours before the study day both at baseline and follow-up.

Chronic post-ischaemic left ventricular dysfunction in myocardium subtended by a stenotic coronary artery can be improved by revascularisation. This phenomenon of reversible dysfunction has been termed “myocardial hibernation”.1,2 It has been hypothesised that hibernation is an “adaptation” to chronic reduction in resting myocardial blood flow secondary to coronary artery stenosis.3 However, this is contentious as many studies have suggested that basal myocardial blood flow is not significantly reduced even in the presence of severe coronary artery stenoses,4 while there is a progressive reduction of coronary vasodilator reserve with increasing stenosis severity.5 It has also been demonstrated that, in the majority of cases, baseline myocardial perfusion in chronically dysfunctional myocardium which recovers function after revascularisation is similar to that of myocardium with normal contractile function in the same patients and to that of normal healthy subjects. Furthermore, non-infarcted, collateral dependent dysfunctional myocardium has normal resting myocardial perfusion but a reduced coronary vasodilator reserve compared to ischaemic but normally functioning segments.6

Our study aimed to assess non-invasively regional myocardial blood flow and coronary vasodilator reserve in hibernating myocardium before and after coronary revascularisation using positron emission tomography (PET), and to compare them with regions with normal contractile function subtended by a normal coronary artery (remote regions) and myocardium of healthy subjects.
MBF, resting myocardial blood flow (ml/min/g); MBF-dip, myocardial blood flow after dipyridamole (ml/min/g); CVR, coronary vasodilator reserve; MBFcorr, corrected for rate–pressure product; CVRcorr, corrected for rate–pressure product.

All values are mean (SD).

Figure 1 Perfusion data on 163 hibernating myocardial segments before (baseline) and after coronary revascularisation. MBF, myocardial blood flow; MBF-dip, post-dipyridamole myocardial blood flow; CVR, coronary vasodilator reserve. ***p < 0.0001.

A group of 21 age (53(12) years) and sex matched normal volunteers served as controls for the myocardial blood flow and coronary vasodilator reserve measurements. All controls had no history of cardiac disease, a low risk profile, normal physical examination, normal resting ECGs, and negative exercise tests in response to high workloads.

The study was approved by the local ethics committee and written informed consent was obtained by all the patients before the study. The radiation exposure was licensed by the UK administration of radioactive substances advisory committee (ARSAC).

CORONARY ARTERIOGRAPHY

Selective right and left coronary arteriography in multiple views was performed with the Judkins technique. Coronary arteriography was repeated in the nine patients undergoing PTCA three months after the procedure.

RADIONUCLIDE VENTRICULOGRAPHY

LVEF was calculated by radionuclide ventriculography using standard techniques. LVEF was reassessed three months following PTCA and six months following CABG. The analysis was performed by two experienced physicians blinded to all clinical details. The inter-observer and intra-observer agreement was assessed8 in a random subset of 10 patients. The mean of the differences in LVEF was 0.05 (1.5)% points and the 95% limits of agreement were 2.9–3%. 

TRANSTHORACIC ECHOCARDIOGRAPHY

Standard views were acquired. Resting wall motion/thickening was reassessed three months following PTCA (9 patients) and six months following CABG (21 patients). All the studies were performed by an experienced echocardiographer blinded to all the clinical details of the patients. Images were stored on conventional VHS tapes and analysed off-line by continuous display by two experienced observers who were blinded to the clinical, angiographic, and previous echocardiographic results of the patients. For analysis of wall motion, the left ventricle was divided in 16 segments. Regional wall motion/thickening was assessed for each segment and systolic wall motion was graded using a semiquantitative scoring system (American Society of Echocardiography): 1 = normal; 2 = hypokinetic; 3 = akinetic; 4 = dyskinetic. Dysfunctional segments improving wall motion at least one point at the follow up study were considered hibernating. In a random subset of 10 patients the inter-observer and the intra-observer agreement was assessed: inter-observer $\kappa = 0.82$ (95% confidence interval (CI) 0.69 to 0.95); intra-observer $\kappa = 0.90$ (95% CI 0.80 to 1.00).

PET MEASUREMENTS OF MYOCARDIAL BLOOD FLOW AND CORONARY VASODILATOR RESERVE

The PET studies were performed in the patients before revascularisation, three months after PTCA or six months after CABG, and in the control subjects using an ECAT 931-08/12 scanner (CTI Inc, Knoxville, Tennessee, USA). Myocardial blood flow (MBF, ml/min/g) was measured using H15O as previously reported. Measurements were made at rest and two minutes after intravenous administration of dipyridamole (0.56 mg/kg over four minutes, MBF-dip). Coronary vasodilator reserve was calculated as the ratio of post-dipyridamole myocardial blood flow to myocardial blood flow at baseline (MBF-dip/MBF). Because baseline myocardial blood flow is closely related to the rate–pressure product (RPP), an index of myocardial oxygen consumption, basal flow data were also corrected for the RPP using the following equation: MBFcorr = MBF $\times$ (mean patient RPP/individual RPP).

 Reconstruction and analysis of the PET images was performed as previously described. Images were re-sliced in the short axis view and the left ventricle was divided into 16 segments comparable to the echo images, as previously described.

STATISTICAL ANALYSIS

Data are expressed as mean (1 SD). Paired data were compared with the paired t test.

See table 1 for key to abbreviations.
Simultaneous comparison of more than two sets of data was made using one way analysis of variance, followed by the Tukey-Kramer test to identify the source of variation. Significance was assumed for a probability value of $p < 0.05$ (two tailed).

Results

Left Ventricular Functional Outcome

A total of 431 left ventricle segments were assessed by PET and echocardiography. Of these, 48 manifested normal contractile function and were subtended by a normal coronary artery (remote regions) and 383 segments were subtended by a stenotic (> 70%) coronary artery. Of these 383 segments, 370 were revascularised. Nine segments were excluded because of restenosis of the subtending vessel three months after PTCA. Of the remaining 361 revascularised segments, 275 were dysfunctional and 86 had normal baseline wall motion. At follow up 163/275 (59%) of dysfunctional segments improved contractile function (hibernating segments) while dysfunction in the remaining 112 segments remained unchanged. The global LVEF increased from 30 (11)% to 37 (10)%

Myocardial Blood Flow and Coronary Vasodilator Reserve

Controls

In the normal subjects, blood flow was homogeneously distributed in the different ventricular regions, and the mean baseline myocardial blood flow was 0.99 (0.21) ml/min/g, increasing to 3.1 (1.3) ml/min/g after dipyridamole, giving a coronary vasodilator reserve of 3.2 (1.5). The rate–pressure product was 8037 (1798). After correction for the rate–pressure product, myocardial blood flow was 1.03 (0.29) ml/min/g and coronary vasodilator reserve was 3.2 (1.6).

Patients

In the patients the rate–pressure product before revascularisation was 9337 (2250) and after revascularisation was 8443 (1749) ($p = 0.1$ vs controls and pre-revascularisation). In the hibernating segments the baseline myocardial blood flow was unchanged after revascularisation while there was a significant increase in the post-dipyridamole myocardial perfusion and the coronary vasodilator reserve (table 1, fig 1). In the remote regions there were no changes in baseline and post-dipyridamole myocardial blood flow and coronary vasodilator reserve after revascularisation (table 2).
The baseline myocardial blood flow values before and after revascularisation in hibernating, remote, and control segments were not significantly different (fig 2).

The baseline myocardial blood flow of controls (corrected for RPP minus 2 SD) was used. Only 10/163 (6%) hibernating segments had myocardial blood flow lower than this threshold before revascularisation (fig 3).

All pre and post-revascularisation perfusion parameters for hibernating, remote, and control segments are compared in figs 4 and 3.

Discussion
The main finding of this study is that revascularisation of hibernating myocardium is associated with an increase in coronary vasodilator reserve, while the baseline myocardial blood flow remains unchanged. Furthermore, our data show that in more than 90% of hibernating segments the myocardial blood flow before revascularisation is within normal range while the coronary vasodilator reserve is significantly lower than in remote regions (in the same patients) and the myocardium of healthy subjects (controls). Previous studies have also demonstrated that the myocardial blood flow of hibernating segments is similar to that of remote regions or healthy control subjects. Furthermore, Vanoverschelde and colleagues demonstrated in a small and selected group of patients that the pre-revascularisation coronary vasodilator reserve is reduced in dysfunctional myocardium proved to be hibernating by post-revascularisation contractile improvement. Our work confirms and expands these findings by providing post-revascularisation data on myocardial blood flow and coronary vasodilator reserve.

Our findings suggest that chronic post-ischaemic left ventricular dysfunction is not necessarily caused by a chronic reduction in resting blood flow (hibernation in its classical definition), but may be related to a reduction in coronary vasodilator reserve. Reduced coronary vasodilator reserve may result in stress induced left ventricular dysfunction. There is evidence both in animals and humans that this left ventricular dysfunction persists in the post-ischaemic period despite absence of irreversible damage and in the presence of normal or near normal myocardial blood, and has been termed myocardial stunning. In these cases, chronic ventricular dysfunction may be the result of repetitive episodes of imbalance between the supply and demand for oxygen caused by either a temporary increase in myocardial demands (that is, exercise inducible ischaemia) or by oscillations in the blood supply (that is, unstable coronary plaques). Repeated episodes of myocardial ischaemia, occurring during daily life activity, have been documented in patients with chronic stable coronary artery disease. These authors demonstrated ischaemic events to be common and often asymptomatic (73% of cases) lasting between one and 90 minutes. Persistent left ventricular dysfunction following exercise has also been detected in patients with coronary artery disease. Furthermore, a cumulative adverse effect on left ventricular dysfunction of repetitive episodes of ischaemia has been demonstrated in animal models of progressive coronary stenosis and confirmed in patients with coronary artery disease. Repetitive episodes of exercise induced ischaemia, followed by stunning, may thus result in a cumulative effect on post-ischaemic myocardial dysfunction, leading to a chronic state of dysfunction.

It could be hypothesised that improvement of contractile function in hibernating myocardium following coronary revascularisation is caused by the improvement in coronary vasodilator reserve, with a reduction of the “repetitive ischaemic events”. This may trigger cellular mechanisms to “revert” the ultrastructural and metabolic adaptations resulting from repetitive stunning, thus resulting in an improvement in contractility.

We have used H3O for the measurement of myocardial blood flow; this tracer—unlike 15O—is not taken up by scar tissue, thus avoiding the dilution effect of scar.

In our study, both the coronary vasodilator reserve of left ventricle segments subtended by an angiographically normal coronary vessel and with normal contractile function (remote regions), and that of hibernating segments after revascularisation, was significantly lower than the coronary vasodilator reserve of controls. These findings are consistent with previous studies demonstrating an abnormal coronary vasodilator reserve in patients with coronary artery disease, even in regions subtended by normal epicardial coronary vessels. Although the mechanism underlying this phenomenon remains unknown, others have explained it as a manifestation of microvascular endothelial dysfunction which affects patients with coronary artery disease.

Study Limitations
In this study we assessed myocardial blood flow, coronary vasodilator reserve, and regional left ventricular function at a single postoperative time point. Serial temporal studies of these parameters could have provided some insight into the time course of improvement in coronary vasodilator reserve and left ventricular function. Although our study demonstrates that hibernating myocardium is associated with a reduced coronary vasodilator reserve, because of the resolution limitations of the current PET scanners we were unable to measure epicardial and endocardial myocardial blood flow and coronary vasodilator reserve, and thus ascertain the implications of these data for the pathophysiology of hibernation. The choice of 0.45 ml/min/g as a lower limit of myocardial blood flow; this tracer—unlike 15O—is not taken up by scar tissue, thus avoiding the dilution effect of scar.
