The technique of transatrial
transpulmonary repair in our
group has undergone transatrial–transpulmonary repair in our
institution.

Objective: To compare actual with predicted long term growth after early repair of tetralogy of Fallot (TOF).

Design: Serial preoperative and postoperative anthropometric data were converted with z scores. The
presence of restrictive physiology was assessed by echocardiography.

Patients: 45 otherwise healthy patients who underwent repair at median age 1.6 years (range 0.2–4.9)
were studied. Predicted height was determined from mid-parental height corrected for sex.

Results: Mean (SD) weight and height z scores at the time of surgery were significantly depressed (−1.04
(0.82) and −0.93 (0.95), respectively; p < 0.0001 for both). At latest follow up at a median age of 14.2
years (range 11–20.5), mean weight and height z scores were 0.16 (1.1) and −0.05 (0.81) (p = 0.32
and p = 0.41, respectively). The improvement between surgical and late weight and height z scores was
significant (p < 0.0001 for each comparison). Catch up growth was largely complete within two years.
Age at correction, duration of follow up, and prior surgical procedures were unrelated to growth. Mean
current height z scores were similar to those predicted by mid-parental height. Patients with restrictive right
ventricular physiology (n = 24) had a significantly greater late z score for weight (0.49 v −0.34;
p = 0.01), with a similar trend for height. Low birth weight patients experienced comparable catch up
growth but remained shorter than patients with normal birth weight (mean height z score −0.64 v 0.06;
p = 0.03).

Conclusions: Early repair of TOF results in significant acceleration of weight and height, with
normalisation of long term growth and fulfilment of genetic growth potential.

METHODS

Consecutive patients resident in the Australian state of Victoria with TOF repaired before the age of 5 years, between
1981 and 1990, were invited to participate in the study. Patients with significant extracardiac or chromosomal
abnormalities and those with atrioventricular septal defect in addition to TOF were not recruited into the study. All
prospective patients had a fluorescence in situ hybridisation test for chromosomal 22q11 microdeletion.

Anthropometric data were obtained from childhood community health record books, which are issued to every
newborn and updated by health carers and community nurses. Perioperative data were taken from perfusion records.
Additional postoperative weight and height measurements were collected from outpatient clinic visits. These data were
converted to z scores by using standard growth data. Mean z scores were calculated by summation of individual z scores,
and the change in mean z scores at different time points was calculated by summing the changes in individual z scores.
Low birth weight was defined as a birth z score below −1.28 (corresponding to the 10th centile for gestational age).
Parental height was also measured at the time of assessment. The predicted height of patients was calculated by the
standard formula for mid-parental height and then corrected for sex.

Echocardiography was performed with a Hewlett Packard 5950 (Hewlett Packard, Andover, Massachusetts, USA) with
ECG and respiratory monitoring. The presence of restrictive right ventricular (RV) physiology was defined as significant

Abbreviations: RV, right ventricular; TGA, transposition of the great
arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect
antegrade diastolic flow in the pulmonary artery coincident with atrial systole and present throughout the respiratory cycle, resulting in cessation of pulmonary regurgitant flow. Pulmonary regurgitation was considered significant if flow reversal in the distal branch pulmonary arteries was present on colour flow mapping.

Abnormally distributed data sets were described by the median (range) and normally distributed data sets by mean (SD). A t test was used to compare mean z scores between groups and at different times, as well as with the reference normal population with a mean of 0. A probability value of p < 0.05 was considered significant.

RESULTS

Among 49 patients available for study, three were excluded from further analysis because of the presence of a 22q11 microdeletion and one patient because of chronic bronchiectasis. Table 1 lists the characteristics of the remaining 45 patients who constituted the study population. At latest follow up three patients had estimated peak instantaneous Doppler gradients across the RV outflow tract > 40 mm Hg and these were excluded from the analysis for restrictive physiology, which was documented in 24 of the remaining 42 (57%) patients.

Table 2 presents mean height and weight z scores at birth, surgery, and latest follow up. At birth the mean weight z scores were −0.20 and mean length z scores were −0.57. By the time of surgery, mean weight and height z scores were comparably depressed at −1.04 and −0.93, respectively. Mean preoperative weight and height z scores compared with those of a normal population (mean z score 0) were significantly depressed (p < 0.0001 for both). At latest follow up, the mean weight and height z scores were not significantly different from those of the normal population (p = 0.32 and p = 0.41, respectively). The differences between the surgical and postoperative weight and height z scores were highly significant (p < 0.0001 for each) (table 2). Growth parameters at each time period were unrelated to age at surgical repair, need for prior surgical palliation, or duration of follow up. Mean follow up height z scores were marginally greater than those predicted by mid-parental height (actual −0.05, predicted −0.37; p = 0.05). Patients with restrictive RV physiology (n = 24) had a significantly greater mean z score for weight (0.49 v −0.34; p = 0.01), with a similar but non-significant trend for height (0.78 v −0.29; p = 0.16), than those without restrictive physiology at latest follow up. The mean body mass index of patients with and those without restrictive physiology were not significantly different (21.8 kg/m2 with and those without restrictive physiology were not significantly different (p = 0.13).

Figure 1 shows the time course of catch up growth for both weight and height. Catch up growth was fastest within the first 12 months after surgical repair and was essentially complete for both parameters by 24 months.

DISCUSSION

This study found a significant improvement in both weight and height z scores in children undergoing corrective surgery for TOF. Low birth weight patients experienced a similar improvement in both growth parameters, but tended to be lighter and were significantly shorter at latest follow up. Fulfilment of genetic growth potential for the overall group was confirmed by attainment of height z scores in the study population that were similar to those predicted by mean parental height z scores. Patients with restrictive physiology tended to have higher weight but not height z scores at latest follow up. Overall long term growth for this group was significantly better than previously reported for patients with TOF. Other factors that can impair postnatal growth are more closely related to the severity of the haemodynamic disturbance. These include decreased energy intake caused by feeding difficulties, increased energy expenditure, gastrointestinal malabsorption, and inefficient utilisation of energy substrates. The relative contribution of each of these factors may vary from one diagnostic group to another. This may explain the discordant results reported, for example, for

resting energy expenditure. In the present study, the relatively symmetrical depression of preoperative weight and height contrasts with the selective depression of weight seen in infants with congestive heart failure and large VSDs. Approximately half (51%) of the patients in the present study underwent palliation with a systemic–pulmonary shunt before surgical repair. The severity of preoperative hypoxaemia in patients with TOF is highly variable and therefore could not be accurately quantified over an extended time. However, the finding of symmetrically depressed weight and height scores at the time of surgical correction is consistent with previous observations that tissue hypoxaemia independently influences linear growth.

**Timing of surgical repair and postoperative growth**

Several studies have suggested that early surgical repair of cardiac defects is important in offering the best prospects for future growth. When surgery is undertaken beyond infancy, growth may still accelerate somewhat but the potential for catch up is limited. In the natural history study, children undergoing surgical repair of a large VSD beyond two years of age found postoperative weight gains but no improvement in mean height. The rate of catch up growth after repair of a large VSD has been reported to be most rapid in the first few postoperative months and in most cases completed by 6–12 months. Schuurmans and colleagues also showed that weight z scores improved most rapidly within 6–12 months postoperatively. In the present study, most catch up growth occurred during the first postoperative year but mean growth parameters continued to improve during the following year.

Among children with single ventricle physiology, conflicting results have been reported for postoperative growth after cavopulmonary connection or a modified Fontan procedure. These may well have been influenced by the heterogeneous nature of the cardiac malformations and the frequent requirement for repeated interventions, particularly in children with palliated hypoplastic left heart syndrome.

Growth after repair of TOF has been studied less frequently. In the largest study to date, 73 children undergoing repair at a mean age of 83.3 months and followed up for at least two years were studied by Page and colleagues. Only 23 experienced acceleration in both postoperative weight and height, and 11 remained below the third centile for both parameters. Although patients with other medical conditions likely to affect growth were excluded, this may not have applied to patients with 22q11 microdeletion, in view of the era of investigation. Furthermore, patients were much older at the time of surgical repair and the repair was likely to have been by a transventricular approach. The age at surgery and entry criteria in the study by Schuurmans and colleagues were more directly comparable with those of our study. Interestingly, however, although growth improved, it did not normalise completely. The mean weight and height z scores of 11 children with repaired TOF followed up for 36–48 months were −1.22 and −0.76, respectively, compared with 0.16 and −0.05 in the present study. In neither of the studies mentioned above was the growth of low birth weight patients examined separately.

**Influence of restrictive physiology**

Although restrictive RV physiology complicates the initial postoperative period after total repair of TOF, the long term benefits of this phenomenon have been well documented. Within our population those patients with restrictive RV physiology had significantly greater z scores for weight at follow up. This was an unexpected finding and we did not quantify the degree of pulmonary regurgitation in sufficient...
detail to tease out this relation further. A body mass index of 22.2 kg/m² suggests that this finding was not due to a more sedentary lifestyle among those with restrictive physiology. It is also unlikely that these patients were limited by symptoms and therefore less able to exercise. Patients with a restrictive RV may have had more favourable haemodynamic factors resulting in better weight gain during childhood.

Study limitations

Uniform surgical techniques (transatrial— transpulmonary approach) used in our hospital for repair of TOF did not allow determination of whether conventional surgical repair involving right ventriculotomy may be associated with comparable outcomes. It was also not feasible to clarify further the impact of age of surgical intervention on postoperative growth. In the present era, many infants undergo TOF repair before 12 months of age. The benefit of this strategy on long term growth, haemodynamic status, and arrhythmia potential remain to be elucidated. In view of the finding of normal late postoperative growth in the present study, it seems unlikely that earlier surgery would have any additive benefit for long term growth.

Conclusions

Preoperative growth is depressed in children with TOF. After early transatrial—transpulmonary repair, the catch up in both height and weight is significant during the next 24 months, resulting in normalisation of long term growth and fulfilment of genetic growth potential. As with other forms of repaired congenital heart disease, with TOF low birth weight is associated with reduced linear growth at long term follow up.

Increased Nox2 in cardiomyocytes after acute myocardial infarction

For the first time, researchers have identified Nox2 within human cardiomyocytes and shown that its expression increases during acute myocardial infarction. Nox2 is an enzymatic subunit of phagocytic NADPH oxidase. It is a cell specific source of reactive oxygen species (ROS), which in turn can induce cell damage, proliferation, apoptosis, gene expression, and aging.

Investigators from the University of Amsterdam examined cardiomyocytes from infarcted and non-infarcted areas of the hearts of patients dying after an acute myocardial infarct as well as from controls without known heart disease. Western blotting and immunohistochemical techniques proved that Nox2 was present in the plasma membrane and cytosol of cardiomyocytes. It was expressed more in infarcted than in control areas. This upregulation is probably related to production of ROS so may well play an important role in cell damage. Its precise pathophysiological role is ripe for further study.
