More than 800,000 patients undergo coronary artery bypass graft (CABG) surgery worldwide every year. CABG surgery continues to change, with a greater emphasis on arterial grafting, refinements in cardioplegia, and the introduction of minimally invasive surgery with or without the use of cardiopulmonary bypass. Although the overall results of CABG have improved in recent years, revascularisation of the heart is still associated with a risk of perioperative and postoperative death and morbidity. Patients undergoing CABG are now older and a larger number have had previous myocardial infarction (MI), stroke, or heart surgery. Consequently, morbidity and mortality after CABG surgery is expected to increase despite procedural advances.

The objective of this analysis was to quantify the incidence of early postoperative major adverse events (AEs) (MI, stroke, gastrointestinal bleeding, renal failure requiring dialysis, and death) in a standard CABG population. To achieve this objective, we systematically reviewed the published literature to build the evidence base and then performed incidence calculations for various groups of patients defined by all elective and non-elective factors for these AEs.

METHODS
In general, procedures for this review followed established best methods for the evolving science of systematic review research. A protocol was written prospectively, which stated the objectives, search criteria, study selection criteria, data elements of interest, and plans for analysis.

Adverse events in coronary artery bypass graft (CABG) trials: a systematic review and analysis
L Nalysnyk, K Fahrbach, M W Reynolds, S Z Zhao, S Ross

Objective: To quantify the incidence of major adverse events (AEs) occurring in hospital or within 30 days after surgery in patients undergoing coronary artery bypass graft (CABG) surgery and to identify risk factors for these AEs.

Methods: Systematic review and analysis of studies published in English since 1990. Studies of isolated standard CABG reporting postoperative incidence of myocardial infarction (MI), stroke, gastrointestinal bleeding, renal failure, or death in hospital or within 30 days were eligible for inclusion. Incidence of these events was calculated overall and for selected patient groups defined by all elective CABG versus mixed (some non-elective); mean ejection fraction < 50% versus > 50%; mean age < 60 versus > 60 years; primary CABG versus some reoperations; randomised controlled trials versus cohort studies; and single centre versus multicentre studies. Odds ratios of selected AEs were computed according to group risk factors.

Results: 176 studies (205,717 patients) met all inclusion criteria. The average incidence of major AEs occurring in hospital was death (1.7%); non-fatal MI (2.4%); non-fatal stroke (1.3%); gastrointestinal bleeding (1.5%); and renal failure (0.8%). Thirty day mortality was 2.1%. Meta-analyses show that age > 70, female sex, low ejection fraction, history of stroke, MI, or heart surgery, and presence of diabetes or hypertension are all associated with increased 30 day mortality after CABG.

Conclusion: The incidence of major AEs in patients after CABG varies widely across studies and patient populations, and this heterogeneity must be controlled when using the literature to benchmark safety.
reported perioperative outcomes and it was not clear that these occurred after surgery, the study was excluded from our review. Studies reporting only intraoperative events were also excluded.

Database development

Data from all accepted studies were extracted to a data form by one investigator, and all elements were reviewed and agreed upon by a second investigator before data entry. Data elements sought from each accepted study were protocol specified study, patient, and treatment characteristics, and the numbers of patients with AEs of interest. The timing of postoperative AEs reported was also sought as a categorical variable—that is, in hospital or within 30 days after surgery.

Analysis

The primary outcome of interest was the incidence of five specific AEs in CABG groups. For outcomes other than death, non-fatal events were sought, but if only total events (fatal and non-fatal) were reported, these were extracted and analysed separately. The average incidence of MI, stroke, gastrointestinal bleeding, renal failure, and death across studies was estimated by a random effects model (REM) meta-analytical technique\(^2\) using restricted maximum likelihood estimation. The REM assumes heterogeneity of the studies and weighs each study by both its within study sample size and the estimated between study variation in AE incidence. When the between study variation is zero, the REM gives results identical to those of a fixed effects model. Only the REM results are reported, as it is generally a more conservative estimate.

The potential influence on incidence of AEs of study variables (location (North America, Europe, or other); number of study sites (single versus multicentre), study design (RCT versus cohort)) and group variables (timing of CABG (elective versus mixed); mean age (< 60 v ≥ 60 years); ejection fraction (≤ 50% v > 50%), and prior CABG (none v some patients with reoperations)) was also studied. Bivariate meta-regressions were conducted relating selected study characteristics to each of the individual AEs. The computed incidences are presented as mean (SE) and medians.

Many studies reported results stratified by sex, prior condition (for example, prior MI, prior stroke), or age. This allowed us to investigate more precisely the relations between patient level characteristics and the odds of a patient suffering a given AE. Where possible, odds ratios were calculated relating each possible patient characteristic to each reported AE; these odds ratios were meta-analysed using methods similar to those mentioned above.

All calculations were performed using SPSS software version 10.1 (SPSS Inc, Chicago, Illinois, USA) and SAS/IML software version 8.1 (SAS Institute, Cary, North Carolina, USA).

In the following results, “k” refers to the number of studies, “1” to the number of treatment groups, and “n” to the number of patients.

RESULTS

Studies

The literature search including manual bibliography checks yielded 4885 citations. The vast majority were rejected immediately for reasons such as ineligible language or patient population. Full papers were retrieved for 596 abstracts that had no apparent reason for exclusion. Of these, 388 were subsequently rejected for reasons of absence of reporting of AEs of interest, unclear timing of AEs, or mixing of data of patients undergoing CABG and data of patients having valve replacement or other concomitant procedures, or because only late (after 30 days) postoperative AEs were reported. In addition, several publications reported on the same patient population (kin studies), and these were extracted as one study to avoid double counting of results. Therefore, 176 primary and 32 kin studies were found to satisfy all inclusion criteria and were included in this review. A citation list of 176 primary studies is provided in the appendix on the Heart website.

The accepted studies were conducted in Europe (k = 54, n = 34 437) and North America (k = 91, n = 154 524), and 31 (n = 16 706) were multinational trials or studies conducted in other geographic locations. There were 69 RCTs (n = 9598), 13 non-RCTs (n = 2019), and 94 cohort studies (n = 194 050). The majority of studies were conducted in a single centre (k = 146, n = 105 104) and 30 studies (n = 100 563) were multicentre trials evaluating in total approximately the same number of patients as all the single centre studies. Most of the studies were published very recently, after 1995 (k = 135).

Patient and treatment characteristics

Table 1 summarises baseline and operative patient characteristics. There were 176 treatment groups overall, comprising 205 667 patients. The majority of patients in all studies were men (81.6%). The average age of all patients ranged from 35–71.3 years with the overall mean being 62.8 years. In the 31 studies reporting New York Heart Association (NYHA) classification, more than half of all patients (67.6%) were in NYHA class II or IV. Approximately 10% of patients in this set of studies had low left ventricular ejection fraction (< 35–40%).

Table 1 also shows the prevalence of comorbid conditions and risk factors among patients in these studies. More than 50% of patients in groups reporting this information had hypertension or high cholesterol concentration (52.1% and 54.2%, respectively). Previous MI was reported by 46.7% and unstable angina by 32.1% of patients in groups reporting these histories. There was also a significant proportion of patients who had previous CABG or revascularisation (5.8% and 6.1%, respectively).

CABG surgery was urgent or an emergency in 28% of patients in 115 studies. During CABG, patients received an average of 3.2 grafts (range of means 1–4.3). Only two studies were single graft studies.

In-hospital adverse events

Table 2 displays the incidences of in-hospital AEs. MI, both all MIs and non-fatal MIs, was the most prevalent AE in the overall CABG population and across all stratified categories. Because of the various diagnostic criteria used to define MI, the incidence of MI differs widely across the studies, from 0–29.2% with the average of 3.9% (median 2.9%). In five studies (all RCTs) it was greater than 10% (Carrier 1998, Menashe 1993, Multicenter Study of Perioperative Ischemia 1995, Mullis-Jansson 1999, and Searle 1996). The incidence of MI differed significantly between RCTs and cohort studies (6.3% v 2.7%, p < 0.05) and between single centre and multicentre studies (2.8% v 7.9%, p < 0.01). A greater incidence of MI was found in studies enrolling patients with prior CABG than in those without prior CABG (6.5% v 2.7%), but this did not reach significance. Non-fatal MI occurred on average in 2.4% (median 2.4%, range 0–13.9%) of the overall CABG patients and was slightly lower in elective CABG than in mixed (2.3% v 2.6%). Interestingly, older age (> 60 years) and lower mean ejection fraction (< 50%) were not associated with a higher incidence of MI.

Non-fatal strokes occurred in 1.3% (median 1.3%, range 0–3.2%) of patients and the incidence was lower in groups with elective surgery (1.0% v 1.5%) and no prior CABG (1.0% v 1.8%), and it was significantly lower in RCTs than in cohort studies (1.0% v 1.5%, p < 0.01). Surprisingly, in studies that did not distinguish between fatal and non-fatal strokes (strokes), the rate appeared to be higher in younger groups (mean age ≤ 60 years, 2.8% v 1.9%), but it was not significant.
Gastrointestinal bleeding was reported by only eight studies. Overall, the incidence of gastrointestinal bleeding after CABG among 12,897 patients was 1.5% (median 1.2%, range 0.7–2.7%). Patients without prior CABG appeared to have a higher incidence of gastrointestinal bleeding than the groups where some patients had prior bypass surgery (2.6% vs 1.5%). But, with so few studies, no differences were significant in the incidence of gastrointestinal bleeding with respect to any of the variables assessed.

The incidence of renal failure requiring dialysis was low. In 23 studies (n = 22,798) on average 0.8% (median 0.7%, range 0–6.2%) of patients needed dialysis after CABG. The frequency was higher in studies enrolling patients with urgent or emergency CABG than in elective CABG only (0.9% vs 0.5%) and it was significantly higher in cohort studies than in RCTs (1.0% vs 0.4%, p < 0.05).

Postoperative mortality rate during hospital stay was 1.7% (median 1.5%) in the overall CABG population and ranged from 0–6.6%. When studies were stratified as elective versus mixed (including patients with urgent or emergency CABG), the mortality rate was significantly lower in the elective CABG (1.5% vs 1.8%, p < 0.05). In-hospital mortality rate was higher in studies enrolling older patients (mean age > 60 years, 1.8% vs 1.2%) and in patients with no history of prior CABG (1.2% vs 1.9%). A significantly lower incidence of death was also noted in RCTs than in cohort studies (1.5% vs 1.8%, p < 0.05) and in single centre studies than in multicentre studies (1.5% vs 2.5%, p < 0.05).

%: percentage of patients with this characteristic in treatment groups reporting this characteristic; CABG, coronary artery bypass grafting; CVD, cardiovascular disease; F, female; k, number of studies reporting this characteristic; LVEF, left ventricular ejection fraction; M, male; n, number of patients in groups reporting this characteristic; MI, myocardial infarction; NYHA, New York Heart Association; PTCA, percutaneous transluminal coronary angioplasty.

The 30 day outcomes for MI, stroke, gastrointestinal bleeding, and renal failure were reported too infrequently; therefore, a meta-analysis of the incidence of these events was not performed.

Sensitivity analysis

Since the incidence of major AEs after CABG surgery appears to differ in RCTs and cohort studies, we performed similar stratified analyses for all outcomes of interest separately for RCTs and cohort studies. These findings were consistent with the overall analysis of the incidence of major AEs after CABG and further confirmed the potential influence of some study variables (geographic location, number of study centres) and group variables (elective CABG only versus some patients with urgent of emergency CABG, some patients with a history of prior CABG versus primary CABG).

The potential impact of cardiopulmonary bypass duration on patient outcomes was tested in the meta-regression analysis. A weak but significant positive relation (\( p = 0.02 \)) was noted between cardiopulmonary bypass duration and incidence of non-fatal MI. There was no significant relation between cardiopulmonary bypass duration and any of the other outcomes. It should be noted that the lack of significant findings does not imply that there is no relation between cardiopulmonary bypass duration and increased risk of AEs at the patient level. The metaregression can only investigate the study level relation between mean cardiopulmonary bypass duration and incidence of AEs, and thus this investigation has much lower power than an individual patient analysis would have.

Analysis of risk factors

In the set of 176 studies accepted in this review, there were 22 studies in which either risk factor odds ratios were reported for the AEs of interest or the information on these was available and it was possible to calculate the odds ratio of interest. Table 3 shows the individual study odds ratios and meta-analytical results for 30 day mortality by risk factors. These results clearly suggest that old age, female sex, presence of diabetes and hypertension, and history of prior heart surgery and MI are associated with increased risk of death after CABG. Except for diabetes (too few studies), the same is true for other outcomes. It should be noted that the lack of significant findings does not imply that there is no relation between cardiopulmonary bypass duration and incidence of AEs, and thus this investigation has much lower power than an individual patient analysis would have.
stroke (data not shown). The data were too sparse to perform similar meta-analyses for MI and renal failure; however, evidence suggests that female sex, age, and diabetes are positively related to incidence of renal failure after CABG.

**DISCUSSION**

This systematic review and exploration of early postoperative AEs in 176 conventional CABG surgery studies of more than 200,000 patients shows that the incidence of in-hospital death and major AEs varies highly depending on study features such as year, number of centres involved, and study design, as well as patient group characteristics such as age, prior CABG, and timing of operation (elective only or mixed). These differences have now been quantified and must be recognised when interpreting AEs in individual CABG trials and when planning such studies.

The impact of study design was of particular interest in view of the recent debate on the relative merits of RCTs and observational studies. The much higher incidence of MI in RCTs than in cohort studies may be explained by closer monitoring of patients and more sensitive and aggressive detection methods in RCTs. The lower incidence of non-fatal stroke,

www.heartjn.com
gastrointestinal bleeding, and renal failure in the RCTs may be explained by the exclusion of high risk patients. In this review the majority of RCTs excluded patients with prior CABG, low ejection fraction, history of stroke or cerebrovascular disease, or age over 75 years. On the other hand, the large observational studies were usually performed on consecutive patients undergoing CABG in a single institution over a defined period of time. These cohort studies were expected to include a higher proportion of high risk patients, perhaps providing more “real world” results.

Furthermore, differences in AEs associated with differences in operative, anaesthetic, and postoperative techniques were not quantified in this review but should also be considered. What is “standard” or “conventional” CABG varies not just by year but by each centre and surgeon. We observed differences in the type of cardioplegia (warm or cold), bypass time, number and types of conduits used, time in the intensive care unit, extubation practices (early or late), and pain management, all of which may affect AE rates in the postoperative period. Ancillary medications surely differ also, especially with respect to use of antiplatelet agents, heparin, and anticoagulants, but these details were not typically reported. These factors may well contribute to the considerable variation in the reported incidence of major AEs, even when controlling for operative, anaesthetic, and postoperative techniques were not quantified in this review but should also be considered. These factors may well contribute to the considerable variation in the reported incidence of major AEs, even when controlling for these studies could not be used in the stratified and regression analyses. Terms that were frequently used and rarely defined were “perioperative”, “urgent” and “emergent”, “stroke”, and “renal failure”, to name a few.

Lastly, aside from providing a benchmark for AE incidences, this systematic review reinforces the need for future trialists to adopt uniform definitions and terminology, and always to provide a minimum base set of risk factors, perhaps those identified by the Society of Thoracic Surgeons.11

IMAGES IN CARDIOLOGY

Transcatheter closure of large fistula between left main coronary artery and right atrium using Amplatzer duct occluder

A 4 year old girl was admitted with cyanosis after exercise. Physical examination found a continuous murmur which was loudest in the upper right parasternal region. The ECG was normal. Transthoracic echocardiography revealed mild right ventricular and atrial dilatation; it also revealed a fistula originating from the left main coronary artery (LMCA), rounding the ascending aorta and left atrium, and emptying into the right atrium. Ascending aorta angiography showed the presence of an aneurysmal fistula originating from the left main coronary artery and draining into the right atrium. The diameter of the fistulous orifice was 3.0 mm (upper panel, middle column).

A 5 French JL3.0 angiography catheter was introduced into LMCA. Within the catheter a 0.014 inch guiding wire was inserted into left main coronary artery and crossed the fistula into the right atrium. The guiding wire was caught in the right atrium by the Amplatz “goose neck” snare, and passed through a femoral vein. Over the wire a Mullins sheath was transvenously advanced across the fistula (lower panel, middle column). Then the guiding wire was removed. An 8/6 mm Amplatzer duct occluder (ADO) was advanced within the sheath until it reached the tip. The delivery system was carefully withdrawn until the ADO was opened completely at the atrial end of the fistula (upper panel, right column). Post-deployment angiography showed there was no residual shunting, and the coronary blood flow improved (lower panel, right). The murmur disappeared.

A coronary artery fistula most commonly originates from the right coronary artery, but a fistula originating from the left main coronary artery is rare. Coronary artery fistulae can cause myocardial ischaemia, congestive heart failure, bacterial endocarditis, cardiac arrhythmia, and rupture of aneurysmal fistulae. Treatment options include surgical ligation and coil embolisation. An Amplatzer duct occluder provides another means of treatment.
