Mitrail stenosis (MS) is a common finding in rheumatic heart disease and can lead to enlargement of the left atrium and stasis of blood in this heart chamber. This can lead to an increased risk of clot formation in the left atrium and the left atrial appendage.

In numerous studies to date, various precipitating factors for the formation of a clot inside the left atrium have been identified, including atrial fibrillation (AF) rhythm, left atrial size, duration of symptoms, advanced age, and severity of MS. Furthermore, mitral regurgitation (MR) in conjunction with MS has been mentioned as a factor which reduces the risk of left atrial clot formation.1,4

This study was performed to determine the incidence of left atrial clot in a group of patients who remained in normal sinus rhythm (NSR) and to establish the factors which play a determining role in this process.

METHODS

In this descriptive, analytical study, 203 patients with MS, who presented to our department for percutaneous mitral valvuloplasty or mitral valve surgery from January 2001 to February 2002, were studied. All patients underwent trans-thoracic and transoesophageal echocardiography and the results were recorded and analysed.

RESULTS

Forty three patients (21.3%) were male. Median age was 44.8 (12.3) years. Of the patients studied, 88 patients (43.4%) had pure MS, 47 patients (23.2%) had MS plus MR, and 68 patients (33.5%) had MS associated with other valvar abnormalities. One hundred and seven of the total number of patients (52.7%) had NSR and 96 patients (47.3%) had AF.

In the patients with NSR, 14 patients (13.5%, group A) had a clot whereas in the MS plus MR patients in NSR, three patients (11.5%) revealed clot formation in the left atrium. Although the results revealed less clot in the MS group and 5.2 (0.9) cm in the AF group; the difference was significant (p = 0.001). Concerning the variables of age and valve gradient, the difference between the two groups was significant (table 2).

The hypothesis that coexistence of MR with MS reduces the chances of left atrial clot formation was tested in this study. In the pure MS patients in NSR, seven patients (14.3%) had a clot whereas in the MS plus MR patients in NSR, three patients (11.5%) revealed clot formation in the left atrium. Although the results revealed less clot in the combined MS and MR group, the difference was not significant (χ², p = 0.521).

DISCUSSION

Risk factors for clot formation in MS patients in NSR were evaluated in this study. As mentioned earlier, mitral valve surface area did not reveal a significant relation to clot formation. However, this issue is quite controversial, as a

study from Spain in 2000 revealed a significant relation between small mitral valve surface area and clot formation, with an odds ratio of 0.17. This issue has been supported by other studies and it has even been emphasised that in multivariate analysis, the only independent predictor for left atrial clot formation is mitral valve area. Despite these reports, another study has shown no significant relation between mitral valve area and mean valve gradient, and clot formation. In our study, no meaningful relation was found between left atrial size and the presence of a clot in the left atrium, or between age and clot formation. On the other hand, despite the fact that the mean mitral valve score in the MS group in NSR with a clot was higher than the group without a clot, the difference was not significant.

In a study in China, the presence of a left atrial clot in MS patients with small valve area, large valve gradients, and no MR revealed a moderate to strong statistical relation, but did not reveal a relation to left atrial size. In other reports, however, left atrial size and age were shown to be related to the presence of a clot. Another result of this study was the comparison of clot frequency in patients in NSR with those in AF rhythm. Clotting was more common in the AF group, with the difference being significant, as could be expected. Other studies have also revealed the significant effect of AF rhythm on left atrial clot formation. Age of the patients in AF rhythm in our study was significantly higher than the group in NSR.

Concerning the left atrial size, mitral valve score and valve gradient, obtained values were significantly higher in the AF group compared to the group in NSR. Also concerning the coexistence of MR with MS and its effect on inhibiting clot formation, our study showed a lower percentage of clotting in the pure MS group, although the difference was not significant. This could be because the MR present in the majority of the patients in this study was of mild severity. Despite the fact that left atrial clot is usually sought in MS patients with AF rhythm, MS patients in NSR are also at risk from intra-atrial clot formation. Although this risk is less than the AF rhythm group, it is sufficient to warrant measures for prevention of thromboembolic episodes in this group of patients.
