Cumulative patient effective dose and acute radiation-induced chromosomal DNA damage in children with congenital heart disease

Lamia Ait-Ali,1,2 Maria Grazia Andreassi,1,2 Ilenia Foffa,1,2 Isabella Spadoni,2 Eliseo Vano,3 Eugenio Picano1

ABSTRACT

Background The seventh Committee on “Biological Effects of Ionizing Radiation” (BEIR VII, 2006) underlines “the need of studies of infants who are exposed to diagnostic radiation because catheters have been placed in their hearts”.

Objective To determine the lifetime attributable risk (LAR) of cancer associated with the estimated cumulative radiological dose in 59 children (42 male, age 2.8±3.2 years) with complex congenital heart disease, and to assess chromosomal DNA damage after cardiac catheterisation procedures.

Methods In all patients, the cumulative exposure was estimated as effective dose in milliSv (mSv), and LAR cancer was determined from the BEIR VII report. In a subset of 18 patients (13 male, age 5.2±5.7 years) micronucleus as a biomarker of DNA damage and long-term risk predictor of cancer was assayed before and 2 h after catheterisation procedures.

Results The median life time cumulative effective dose was 7.7 mSv per patient (range 4.6–41.2). Cardiac catheterisation procedures and CT were responsible for 95% of the total effective dose. For a 1-year-old child, the LAR cancer was 1 in 382 (25th to 75th centiles: 1 in 531 to 1 in 187) and 1 in 156 (25th to 75th centiles: 1 in 239 to 1 in 83) for male and female patients, respectively. Median micronucleus values increased significantly after the procedure in comparison with baseline (before 6%, vs after 9%, p=0.02). The median dose–area product value was 20 Gy cm² (range 1–277).

Conclusion Children with congenital heart disease are exposed to a significant cumulative dose. Indirect cancer risk estimations and direct DNA data both emphasise the need for strict radiation dose optimisation in children.

INTRODUCTION

Radiation can be used effectively for diagnosis and treatment, but it can also subsequently cause cancers and other conditions.1 Trends indicate that worldwide population exposure from medical radiation is increasing2–3 and the use of procedures with a high radiation dose continues to grow steadily,4–6 especially in cardiology6–8—and particularly in paediatric cardiology.9 Children are at least four times more sensitive than adults to the induction of cancer, and the proliferation of appropriate and inappropriate examinations with high radiological dose in children has raised concern among the paediatric community10 and regulatory bodies.11–12 The National Academies’ Biological Effects of Ionizing Radiation, 7th Report (BEIR VII, phase 2), presented to the USA Congress in June 2005 and published in 2006, underlines “the need of studies of infants who are exposed to diagnostic radiation because catheters have been placed in their hearts” among priority research needs.12

The BEIR VII report develops risk estimates for cancer from exposure to low-level ionising radiation using the most current data and epidemiological models available, providing a framework for estimating cancer risk associated with radiation exposure from medical exposure.12

The aim of our study was to determine the lifetime attributable risk of cancer (fatal and non-fatal) associated with the estimated lifetime cumulative radiological dose in children with complex congenital heart disease (CHD) by using the BEIR VII estimates.

Since these data provide only indirect population-based estimates, we also evaluated directly whether radiation exposure during cardiac catheterisation procedures can induce chromosomal DNA damage. To this end, a micronucleus assay (MN) was performed as a biomarker of chromosomal damage and intermediate end point of carcinogenesis13–14 before and after radiation exposure.

PATIENTS AND METHODS

Patients

The patient population included 59 consecutive inpatients with complex CHD (42 male, age=2.8±3.2 years) who were admitted in 2007 for cardiac haemodynamic procedures to the G Pasquini Hospital in Massa, Italy. Exclusion criteria included the inability to obtain consent from the child’s parents, and the impossibility of reconstructing an accurate history for both the type and number of radiological procedures.

Thirty-one interventional procedures were performed (10 atrioseptostomy according to Rashkind, two pulmonary branch balloon angioplasties, seven pulmonary valvuloplasties, two aortic valvuloplasties, three patent ductus arteriosus closures, one ventricular septal defect closure, six aortic coarctation balloon angioplasties).

In all patients, a detailed radiological history was also reconstructed. All available paper and electronic records of present and past hospital admissions were analysed using—as the primary source of information—the electronic data bank of our institute.

All past examinations performed outside our institute were recalled by interviewing the patients’ parents at the time of admission and by direct perusal of available medical records of the patient.
Examinations without an available record were not considered. Demographic and clinical characteristics of the studied patients are summarised in table 1. Legal representatives of patients gave their informed consent at the time of admission to grant the use of hospital data for research purposes and specifically for the bioassay study, authorised by the local ethical research committee.

### Indirect estimation of cumulative dose and cancer risk for radiation exposure

For each examination the estimated effective dose in milliSievert (mSv) was derived from average dose values reported by the peer-reviewed literature on effective dose for paediatric ionising procedures.15–19 Representative values and ranges of the effective radiation dose for some diagnostic radiology procedures are presented in table 2.

In order to calculate the cumulative risk of cancer, we used estimates of cancer from BEIR VII released in 2006.12 According to these estimates, it is predicted that for a 10 mSv effective dose in adult approximately one person in 2000 would develop fatal cancer12 and one in 1000 would develop fatal and non-fatal cancer.12 The BEIR VII report estimates that the cancer risk in children is higher than for adults. For instance, the same radiation in the first years of life for boys produces three to four times the cancer risk as exposure between the ages of 20 and 50.12

### Direct dose estimation and MN assay

The MN cytokinesis block assay in human lymphocytes was performed on a randomly selected subset of 18 patients (13 male, age 5.2±5.7 years) without comorbidity, and who had undergone cardiac catheterisation procedures for diagnostic purposes (n=13) and for therapeutic procedures (n=5).

All procedures were performed using the Philips Integris H5000C monoplane with the x-ray tube MRC 200 0508 ROT GS 1001. The dose–area product (DAP) was obtained from a transmission ionisation chamber built into the collimator housing of the radiography tube. The DAP (Gy cm²) is a quantity used to estimate patient doses in fluoroscopy guided procedures and represents the dose in air measured at a given distance from the x-ray tube multiplied by the area of the x-ray beam at that distance.15 20 21

The cumulative DAP for a procedure is a surrogate measurement for the total amount of x-ray energy delivered to the patient, and is considered a valid indicator of a patient’s dose and consequent risk for radiation-induced effects. Effective dose was also estimated by the use of a conversion factor (1.2 mSv Gy⁻¹ cm⁻²) derived from the literature (CF=effective dose/DAP (mSv Gycm⁻²)).12

Venous blood samples were collected at baseline and 2 h after the procedure. Two separate cultures from each sample were set up by mixing 0.3 ml of whole blood with 4.7 ml of RPMI 1640 medium; cultures were incubated at 37°C for 72 h. Cytochalasin B (6 μg/ml) was added 44 h after culture initiation. Cells were then harvested and fixed according to the standard method in use in our laboratory.14 For each sample, 1000 binucleated cells were scored by use of an optical microscope (final magnification ×400) for MN analysis, according to the criteria for MN acceptance.22 We quantified the micronucleated binucleated cell frequency as the number of micronucleated cells per 1000 cells. MN frequency was evaluated by the same three microscopists who had no information as to the identity of patients.

### Statistical analysis

Statistical analyses of the data were conducted with the Stat view statistical package, version 5.0.1. The average dose values of individual examinations were expressed as median and 25th–75th centiles. Differences were evaluated by the Mann–Whitney U test. Because of the skewness of the distributions of MN values, analyses were performed using the logarithmic transformation of data. Results are expressed as mean (±SD). Differences between the means of the two continuous variables were evaluated by the paired Student t test. Regression analysis with the Pearson test was also used to evaluate the relationship between the two continuous variables. A p value <0.05 was considered significant.

### RESULTS

In total, 1548 procedures with ionising radiation were performed during the lifetime of the 59 patients.

On average, each patient underwent a mean of 26.2±26.3 examinations (range 1–150, 25th–75th interquartile range 12–27.7). The number of each type of examinations is given in table 3. The median life time cumulative effective dose was 7.7 mSv per patient (range 4.6–41.2, 25th–75th centiles 5.5–12.3). The estimated median effective dose was not significantly different between male (7.1 mSv, 25th–75th centiles 5.1–12.5 mSv) and female (9.4 mSv, 25th–75th centiles 6.5–18.1 mSv) patients. A positive significant correlation was found between cumulative radiological effective dose and age (r=0.518, p<0.0001).
Median effective DAP values were found to be significantly higher in therapeutic interventions than in diagnostic procedures (93 Gy cm² vs 14 Gy cm², p=0.005). DAP values for all patients studied are presented in table 4. The highest value of DAP dose delivered was found for an interventional procedure involving one aortic coarctation balloon angioplasty (277 Gy cm²).

The median effective MN value was 6% (25th–75th interquartile range 4–7%) at baseline and showed a significant rise at 2 h with a median of 9% (25th–75th interquartile range 8–11%) after procedures (Figure 2). Median MN values were higher than the baseline values for both diagnostic (7% vs 11%, p=0.02) and therapeutic cardiac catheterisation procedures (5% vs 9%, p=0.03). However, we did not observe any relationship between DAP and % MN increase (r=0.1, p=0.74), even after taking into account the patient’s weight (r=0.1, p=0.6).

**DISCUSSION**

The average present-day child with CHD is exposed to a significant cumulative radiological effective dose. The new generation of patients with CHD benefits from the enormous advances in cardiac imaging and interventional cardiology, but also receives an unprecedented radiological exposure, associated with a significant long-term risk of cancer based on the latest risk estimates.

**The rise of imaging testing in children**

We are witnessing a spectacular rise in the potential and versatility of cardiovascular imaging in children. The use of multislice CT is increasing even faster in children than in adults, presumably because of the big advantage of a short exposure time that allows for its use without a sedative. It is estimated that there were at least 6.5 million CT examinations in the USA in the paediatric age band in the year 2006, corresponding with about 15% of all CT examinations. Nuclear cardiology stress testing in children is performed in 30% of US institutions, according to a recent survey of the AHA-ACC. The Spanish Society of Cardiology has published data on paediatric cardiology showing increases in the number of fluoroscopic procedures over the years 2000–4 of between 21% (for dilatation) to 97% (for embolisations).

Figure 1 shows the contribution of various types of medical ionising procedures to the total collective dose. Conventional x-ray examinations represent 95% of the total number of examinations, corresponding to only 5% of the collective effective dose. Three types of procedures were responsible for about 95% of the total collective effective dose: diagnostic catheterisation, interventional catheterisation and CT.

The corresponding estimated lifetime attributable risk of fatal cancer for all combinations of age (ranging from 0 to 15 years) was 1 in 1717 and 1 in 859, for male (receiving 7.1 mSv) and female (receiving 9.4 mSv) patients, respectively.

The lifetime attributable risk (fatal and non-fatal cancer) was 1 in 804 for male subjects, and 1 in 331 for female subjects. However, risks were 1.9–2 times higher for child of 1 year than for a 15 year old.

For a 1-year-old child, the median risk of (fatal and non-fatal) cancer was 1 in 382 (25th to 75th centiles 1 in 531 to 1 in 187) and 1 in 156 (25th to 75th centiles 1 in 239 to 1 in 85) for male and female patients, respectively.

For direct dose estimation in the subset of 18 patients, the median fluoroscopy time during the cardiac catheterisations was 22.8 min (range 3–34) without any significant difference between diagnostic and interventional procedures (p=0.6). The mean DAP value was 45.3±64.8 Gy cm² with a median of 20 Gy cm² and a 25th–75th interquartile range of 12–64 Gy cm².

**Figure 1** The most frequent examinations and total collective dose in congenital heart disease: relative contribution of conventional radiographs, CT, diagnostic catheterisation and interventional radiology to (A) the frequency and (B) the total collective effective dose.
Catheterisation procedures in children are typically more time consuming than adult procedures. For several reasons, procedures are longer in children, especially infants, because many patients have had previous studies and have limited access site; in infants the vessels are smaller and more difficult to cannulate; multiple angiograms in several cardiac chambers, using different views, are often needed.

Special problems of medical radiation in children

The growing use of interventional and non-invasive imaging with ionising radiation in children represents a tremendous benefit for the diagnosis and treatment of small patients. However, there are special problems in children that one may wish to consider. First, for any given dose children are three-to-four times more sensitive than adults to the induction of cancer as they have more rapidly dividing cells than adults and have longer life expectancy. Second, for a given procedure, the effective dose is larger in a small infant than in an adult: the vessels are closer together in small children, resulting in more radiation dose to nearby organs when the area of interest is being imaged. Third, in paediatric cardiology, radiological procedures are practised and/or prescribed by cardiologists, who may sometimes have suboptimal awareness of doses and risks owing to lack of adequate formal radiation training—although it is also true that even radiologists may substantially underestimate radiation doses and risks. Fourth, cardiological examinations deliver the highest organ dose from CT and interventions to lung and breast. In particular, during a cardiac CT the breast dose is about 10 times higher than with cardiac interventional procedures. Recent ICRP 2007 documents left virtually unchanged the whole-body risk estimates, but raised the breast risk factor (ie, the excess probability of fatal cancer) by 210%, from 40 in 1 000 000 per mSv in ICRP 1991 to 124 in 1 000 000 per mSv in ICRP 2007. The same document also raised, albeit less markedly, the lung risk factor by 53%, from 85 to 115 in 1 000 000 per mSv. Although these estimates are clouded by a certain degree of uncertainty in the low-dose range, the epidemiological data in children exposed to medical radiation corroborate the assumption of all major organisations that even low doses can harm the patient, and no safe dose exists.

Comparison with previous radiological and biodosimetric studies

In our patients the main contribution to dose was from interventional procedures and CT (84% and 11% of the average dose, respectively). This picture is broadly consistent with recent data on sources of irradiation for the “average” (non-cardiological) patient and on adult cardiac patients. Our data are also in agreement with the preliminary data presented by the European Heart Survey, which reported an annual effective dose of 0.46 mSv/year in the follow-up of these patients, with about 80% of the dose coming from CT and angiography.

Chromosome aberrations in circulating lymphocytes are an intermediate end point of carcinogenesis and a long-term predictor of cancer, and increased a few hours after a fluoroscopic cardiac procedure in children was reported, in a pioneering study conducted in 1978 by Adams et al. Young adolescents with repaired CHD who were exposed to low-dose diagnostic ionising radiation at age <1 year, have an up to threefold increase in chromosomal aberrations in circulating lymphocytes decades after the exposure. In our study, the indirect population-based estimates of cumulative dose and cancer risk were corroborated by direct measurements of MN increase in a subset of patients. The increase was obvious and consistent, although with substantial variability probably owing to genetic differences in polymorphisms of genes involved in DNA damage and/or repair and an environmental oxidant—antioxidant milieu. This approach provides a direct documentation of radiation genotoxicity and may clear the pathway to individually tailored radiation-sparing or chemopreventive strategies.

Study limitations

The number of patients is relatively small, but they are consecutive and representative of the spectrum of clinical situations met in a contemporary paediatric cardiology and cardiac surgery. An undoubtedly limitation of our study is that the lifetime radiological history was derived from hospital records, when available, and from patient history. This leads unavoidably to an approximation, and possibly to an underestimation, of the total radiological burden.

Another limitation is that there is in the real world a marked variability in the dose of each examination. This variability is highest for interventional procedures. For instance, a percutaneous procedure of closure of patent ductus arteriosus is associated with an average effective dose corresponding to 7.6 mSv, but the individual procedure value may range between 2.1 and 28 mSv.

DAP, dose-area product.
Both these aspects—the recall bias and the adoption of typical dose values from the literature rather than true measured values—might have affected the precision of individual patient dose estimation, but are unlikely to substantively affect the order of magnitude of observed values. In addition, we integrated the history-based approach, based upon indirect assessment of doses and population-based estimates of risks, with a direct, patient-based, individual assessment of patient dose and of acute radiation damage through direct biodosimetry with MN assay and faithful radiation dose measurement with DAP. The two approaches are conceptually complementary and seem to point in the same direction, indicating that potentially oncogenic radiation-induced damage is not negligible in these children.

Clinical implications: justify and optimise

Although the benefits of imaging are immense, it is also possible that not all these examinations are entirely appropriate and that there is a suboptimal management of radiological doses (and long-term cancer risks) in everyday clinical practice of paediatric cardiology. The radiation concern is particularly important in our patients with CHD for three reasons. First, adult grown-up patients with surgically repaired CHD are a large and growing population, estimated to be one million in US in the year 2000 compared with an estimated 500 000 in 1980, and 1.4 million are expected by 2020.35 Second, the long-term outcome of the underlying cardiac disease has been dramatically improved by interventions in the past decade, and now excellent long-term survival is the rule, rather than the exception.9 10 Third, and most importantly, children are several times more sensitive to radiation than middle-aged adults.11 12 Therefore, when managing today a serious condition such as a complex CHD, we have also to protect the patient from risks that may become clinically manifest after years and even decades. We should justify the indication and optimise the dose delivery, adjusting doses, reducing multiple scans with contrast material and eliminating inappropriate referrals.

For instance, the application of currently available dose-reduction techniques for heart scan and invasive cardiology could be strongly applied in daily practice in order to allow a reduction of patient doses while maintaining the image quality.40 41 These practice patterns were recommended by the FDA, the European Union referral guidelines for imaging and by the recent white paper of the American College of Radiology.42 In Europe the justification, optimisation and responsibility principles are also reinforced by the Euratom law.43 The challenge ahead is to implement these recommendations universally in clinical practice.

Competing interests None.
