**ABSTRACT**  
**Objective** To examine the association of lipid-lowering drugs, change in diet and physical activity with a decline in low-density lipoprotein (LDL) cholesterol in middle age.  
**Design** A prospective cohort study.  
**Setting** The Whitehall II study.  
**Participants** 4469 British civil servants (72% men) aged 39–62 years at baseline.  
**Main Outcome Measure** Change in LDL-cholesterol concentrations between the baseline (1991–3) and follow-up (2003–4).  
**Results** Mean LDL-cholesterol decreased from 4.38 to 3.52 mmol/l over a mean follow-up of 11.3 years. In a mutually adjusted model, a decline in LDL-cholesterol was greater among those who were taking lipid-lowering treatment at baseline (−1.14 mmol/l, n=34), or started treatment during the follow-up (−1.77 mmol/l, n=481) compared with untreated individuals (n=3954; p<0.001); among those who improved their diet—especially the ratio of white to red meat consumption and the ratio of polyunsaturated to saturated fatty acids intake—(−0.07 mmol/l, n=717) compared with those with no change in diet (n=3071; p=0.03) and among those who increased physical activity (−0.10 mmol/l, n=601) compared with those with no change in physical activity (n=3312; p=0.005). Based on these estimates, successful implementation of lipid-lowering drug treatment for high-risk participants (n=858) and favourable changes in diet (n=3457) and physical activity (n=2190) among those with non-optimal lifestyles would reduce LDL-cholesterol by 0.90 to 1.07 mmol/l in the total cohort.  
**Conclusions** Both lipid-lowering pharmacotherapy and favourable changes in lifestyle independently reduced LDL-cholesterol levels in a cohort of middle-aged men and women, supporting the use of multifaceted intervention strategies for prevention.

Blood cholesterol, low density lipoprotein (LDL) cholesterol in particular, is a major risk factor for coronary heart disease (CHD).1 Large randomised controlled trials and meta-analyses2–4 have established the clinical benefits of lowering LDL-cholesterol. A decrease of 1 mmol/l in LDL-cholesterol concentrations has been shown to be associated with a 23% lower risk of myocardial infarction or coronary death.4 Similarly, a 10% reduction in total cholesterol was associated with a 20% reduction in the risk of CHD.5

There is now consistent evidence for a secular decline in total cholesterol and LDL-cholesterol levels among adults in industrialised countries.6–13 For example, the MONICA study showed total cholesterol in adults aged 35–64 years to have declined between the mid-1980s and mid-1990s in approximately half of the European populations included in the study.6 Similar findings have been reported in other European populations,6–12 the USA,13–16 Canada,17 Australia18 and New Zealand.19

Clinical guidelines recommend a multifaceted approach to lowering LDL-cholesterol.1,20 However, the extent to which a healthy diet, physical activity and lipid-lowering drugs independently explain the decline in LDL-cholesterol levels currently being observed at the population level is unknown. We therefore examined associations of lipid-lowering drug use and 11-year change in diet and physical activity with declining LDL-cholesterol trends in an occupational cohort of middle-aged British civil servants participating in the Whitehall II study.

**SUBJECTS AND METHODS**  
**Study sample**  

Detailed lipid data were not available at phase 1 so the data used in the current analysis were drawn from phases 3–7, making phase 5 the baseline for the present study. The mean follow-up between phases 3 and 7 was 11.3 years (SD=0.5). Participants not included in the analysis were those who did not undertake the medical screening at phases 5 or 7, and those with missing data on any of the predictors (lipid-lowering drugs, diet and physical activity) or potential confounders (ethnicity, body mass index, level of education, smoking status and the presence of long-standing illness) either at phase 3 or phase 7 (figure 1). A total of 4469 participants was eligible and constituted the study sample. Ethical approval for the Whitehall II study...
Epidemiology

Phase 1 (1985-1988) respondents (n=10 308)
Excluded (n=2493):
Died (n=107)
Lost to follow-up (n=1)
Non respondents at phase 3 (n=1385)

Phase 3 (1991-1993) respondents (n=8815)
Excluded (n=1232):
Missed screening or questionnaire (n=885)
Missing LDL-C despite attending screening (n=211)
Missing diet data (n=62)
Missing physical activity data (n=55)
Missing BMI (n=23)
Missing data on smoking status (n=3)

Included at phase 3 (n=7583)

Phase 7 (2003-2004) respondents (n=6075)
Excluded (n=1606):
Missed screening or questionnaire (n=375)
Missing LDL-C despite attending screening (n=115)
Missing lipid lowering drug data (n=2)
Missing diet data (n=727)
Missing physical activity data (n=67)
Missing BMI (n=22)
Missing ApoE genotype (n=249)
Missing data on education (n=220)
Missing data on smoking status (n=7)
Missing data on presence of longstanding illness (n=4)

Included at phase 7 (n=4469)

Figure 1 Selection of the study participants. ApoE, apolipoprotein E; BMI, body mass index; LDL-C, low-density lipoprotein cholesterol.

was obtained from the University College London Medical School committee on the ethics of human research (London, UK).

Biochemical analyses

Blood samples were collected at phases 3 and 7, following either an 8-h overnight fast (participants presenting to the clinic in the morning) or at least a 4-h fast after a light fat-free breakfast (participants presenting in the afternoon). Venepuncture of the left antecubital vein was performed with tourniquet. Blood was collected into plain and fluoride Sarstedt (Neumbrecht, Germany) monovettes. Serum for lipid analyses was refrigerated at $-4^\circ$C and assayed within 72 h. Total cholesterol was determined by an enzymatic procedure using the CHOD–PAP method at phases 3 and 7. Serum high-density lipoprotein (HDL) cholesterol concentrations were measured from the supernatant after the precipitation of non-HDL-cholesterol with (HDL) cholesterol concentrations were measured from the method at phases 3 and 7. Serum high-density lipoprotein determined by an enzymatic procedure using the CHOD duplicate samples for 5% of subjects. Coefficients of variation were 2.0–6.6%. After both screenings, participants were sent a letter that informed them of their results and summarised whether or not they were ‘at increased risk of heart disease or angina’. For example, when a total cholesterol level of 8.5 mmol/l or higher was recorded at baseline (n=185), the letter suggested the participant see his or her general practitioner for a repeat test. The same envelope contained a similar unacond letter addressed to the participant’s general practitioner.

Potential predictors

Lipid-lowering drugs

At phases 3 and 7, participants were asked whether they had taken any medication in the past 14 days and, if so, to provide the name of the medication. Medications were coded using British National Formulary codes. We did not distinguish statins from other lipid-lowering drugs, such as fibrates, nicotinic acid and its derivatives, cholester absorption inhibitors, or omega-3 fatty acid compounds. Our measure thus included all lipid-lowering drugs combined together.

Diet quality using the AHEI

Diet quality was measured using the alternate healthy eating index (AHEI). Based on the 127-item anglicised version of Willett’s food frequency questionnaire (FFQ), it has been found to yield a satisfactory estimate of food intake among Whitehall II participants compared with biomarkers and 7-day diet diaries. The AHEI includes nine food components; food items listed on the FFQ were assigned to their appropriate food groups, using the FFQ serving sizes identified. Eight of the nine components (vegetables, fruit, nuts and soy protein, ratio of white to red meat, dietary fibre, transfat, ratio of polyunsaturated to saturated fatty acids and alcohol) contributed 0–10 points to the total AHEI score. A score of 10 indicates that recommendations were fully met, whereas a score of 0 represents the least healthy dietary behaviour. Intermediate intakes were scored proportionally between 0 and 10. The final component, long-term multivitamin use, was dichotomised, contributing either 2.5 points (for non-use) or 7.5 points (for use) to the total score. All component scores were summed to obtain a total AHEI score ranging from 2.5 (worst) to 87.5 (best). Nutrient intake estimates were calculated using a computerised system developed for the Whitehall II dietary data.

Physical activity

At baseline (phase 3), participants were asked the duration (number of hours per week) of their participation in moderately energetic (eg, dancing, cycling, leisurely swimming, lawn mowing) and vigorous (eg, running, hard swimming, playing squash) physical activity. At phase 7, the questionnaire was modified to include 20 items on the duration of participation in different physical activities (eg, running, cycling, other sports, housework and gardening activities) that were used to compute hours per week at each intensity level. At both phases, physical activity was defined as the total number of hours per week spent in moderate and vigorous activity.

Covariates

Other variables included in the analysis were: sex; age at baseline (<45, 45–54, ≥55 years); self-reported ethnicity (white, non-white); education (none, lower secondary, A-levels, university or higher); current smoking (categorised as yes or no); and long-standing illness (categorised as yes or no). Prevalent CHD was defined using the MONICA criteria, positive responses to questions about chest pain and physician diagnoses, evidence from medical records, or ECG findings. Prevalent diabetes
mellitus was defined as reported doctor-diagnosed diabetes mellitus or the use of diabetes medication.30 Body mass index (BMI) was calculated as weight in kilograms divided by height in metres squared and categorised as normal (BMI <25), overweight (25 ≤BMI <30), or obese (BMI ≥30).31

Statistical analyses
The 11-year change in LDL-cholesterol was calculated as phase 7 minus phase 3 values. In the analysis we wanted to determine the impact of the predictors assessed at baseline (phase 3) and their values over the 11-year follow-up. In order to simplify the interpretation of the coefficients, we categorised the predictors in the following way: lipid-lowering drug use was categorised as no use, treated at baseline, or treatment started during the follow-up. Change in diet was estimated by subtracting the AHEI score at baseline from that at phase 7, standardised to a z-score (mean 0, SD 1) and categorised as ‘increase’ (z-score ≥1), ‘stable’ (−1≤ z-score <1) and ‘decrease’ (z-score ≤−1).

This procedure was first applied to the total AHEI score and then to the nine components of the score. Change in physical activity was calculated by subtracting the number of hours per week of physical activity at baseline from that at phase 7. The difference in duration was standardised and categorised as an ‘increase’ (z-score ≥1), ‘stable’ (−1≤ z-score <1), ‘decrease’ (z-score ≤−1) level of physical activity.

As 11-year changes in LDL-cholesterol, diet score and physical activity were all normally distributed, parametric statistical tests were used in the analysis. To examine the unadjusted impact of the predictors (lipid-lowering drug, diet and physical activity) and the covariates we first conducted univariate analysis using linear regression with change in LDL-cholesterol as the dependent variable. The interaction terms between the predictors and sex and age had p values greater than 0.05, negating any necessity to stratify the analyses by age or sex. For the quantitative predictors (diet and physical activity) and for change in BMI, we tested the interaction between continuous values at baseline and the change measures expressed as ‘increase’, ‘stable’, or ‘decrease’. Only the interaction term between BMI at baseline and change in BMI was significant (p<0.05) and was consequently included in further analyses as a covariate.

We constructed three models to examine associations between the predictors and concomitant change in LDL-cholesterol. Model 1 included only non-modifiable covariates (sex, age at baseline, ethnicity) and the duration of follow-up. Model 2 further included education, BMI and long-standing illness at baseline. Model 3 included all three predictors together with the covariates already in model 2. To examine the role of regression to the mean in declining LDL-cholesterol trends, we repeated model 3 among participants in the highest quintile of LDL-cholesterol at baseline (in this subgroup regression to the mean is particularly likely)32 and compared the results with those from the main analysis. In addition, for lipid-lowering medication we removed any potential regression to the mean effect by comparing those with lipid-lowering medication during follow-up with a group without medication selected such that their mean LDL-cholesterol values at baseline were identical.

Using the covariates and predictors in model 3, we conducted several supplementary analyses to determine: (1) whether specific components of the nine-item AHEI scale were associated with the reduction in LDL-cholesterol; (2) the effect of moderate and vigorous physical activity separately on change in LDL-cholesterol; (3) the impact of further adjusting model 3 for change in BMI and the interaction term between change in BMI and BMI at baseline; and (4) whether replacing the variable ‘presence of a long-standing illness at baseline’ by the variables ‘presence of at least one non-fatal CHD event at baseline’ and ‘presence of diabetes mellitus at baseline’ changed estimates.

The squared multiple correlation, also called coefficient of determination ($R^2$), was used to estimate the proportion of variation in LDL-cholesterol change explained by the predictors. We assessed change in $R^2$ when each predictor was entered individually into the initial model adjusted for sex, age at baseline, ethnicity, duration of follow-up, education level, BMI at baseline and long-standing illness at baseline; the model above plus mutual adjustment for the predictors.33

To examine potential beneficial effects related to lipid-lowering drug treatment and favourable changes in diet and physical activity, we estimated the reduction in LDL-cholesterol that would be observed if all participants in need of lipid-lowering drugs at baseline (n=858) were treated, all individuals with a non-optimal diet (AHEI score <60, n=3457) improved their diet, defined as an increased AHEI score of at least 1 SD (0.6 point), and those who undertake less than the recommended level of physical activity (<2.5 h/week, n=2190) increased their physical activity, defined as a minimum increase of 17 min (1 SD) physical activity per week. Following European guidelines,32 participants with prevalent CHD or diabetes and those with a ‘high risk’ of cardiovascular disease (CVD) defined as having a 10-year risk of CVD death of 5% or more based on the systematic coronary risk evaluation (SCORE) charts,34 were deemed to be in need of lipid-lowering therapy. The benefits of lipid-lowering treatment, improved diet (≥1 SD) and increased physical activity levels (≥1 SD) for the total population were estimated based on model 3 estimates using the following equation:

$$\hat{y} = \text{intercept} + \beta_1 \text{treatment at baseline} + \beta_2 \text{treatment during the follow-up} + \beta_3 \text{1 SD} \text{ in AHEI score} + \beta_4 \text{1 SD} \text{ in hours of physical activity} + \beta_5 \text{one or more SD decrease in AHEI score} + \beta_6 \text{one or more SD decrease in hours of physical activity} + \beta_7 \text{men} + \beta_8 \text{age at baseline} + \beta_9 \text{education} + \beta_10 \text{long-standing illness} + \beta_11 \text{duration of follow-up},$$

where $\hat{y}$ is a change in LDL cholesterol and I an indicator variable (1 vs 0). All analyses were performed using SAS software, version 9.

RESULTS

Description of the study participants
Of the 10 308 participants at recruitment to the study, 7583 had complete data at phase 3 and 4469 were included in the analysis reported here (figure 1, comparison of the participants included in the analyses with those excluded is provided in supplementary appendix, eTable 1, available online only). Table 1 describes the characteristics of those included at baseline and follow-up. The mean age at baseline was 49.5 years and 72.0% were men. From baseline to follow-up, the mean LDL-cholesterol concentration dropped from 4.38 to 3.52 mmol/l. At the same time the use of lipid-lowering drugs increased from 0.8% to 10.8%. There was a small increase in the mean total AHEI score (from 50.7 to 51.2) and the number of mean hours per week spent in moderate or vigorous physical activity (from 3.4 to 3.7 h/week).

At baseline, 858 participants had a high risk of CVD according to the European guidelines,32 had diabetes or had experienced a validated non-fatal CHD event at baseline, or took lipid-lowering medication at baseline or follow-up. Only 60.0% (n=515) of them were taking lipid-lowering medication at follow-up.
Multivariate analysis of change in lipid levels during follow-up

Univariate analyses provided strong evidence of associations between changes in LDL-cholesterol and all the covariates, with the exception of smoking (see supplementary appendix eTable 2, available online only). Table 2 presents multivariable-adjusted absolute changes in LDL-cholesterol as a function of lipid-lowering medication and changes in diet and physical activity. These results show that LDL-cholesterol declined in all groups. Table 3 shows the corresponding changes in relative terms. Compared with those not on lipid-lowering drugs, the decline in LDL-cholesterol was greater among those who were on treatment at baseline or during the follow-up. Compared with those with a stable diet, individuals who improved their diet showed a greater decline in LDL-cholesterol, whereas those whose diet worsened showed a smaller decline. Similar results were observed for physical activity. All relative differences persisted after serial adjustments for multiple covariates (table 3). The results were largely similar in a subgroup of participants in the top quintile of LDL-cholesterol at baseline and when, for lipid-lowering medication, potential regression to the mean effects were totally removed (see supplementary appendix eTable 3, available online only).

More detailed analyses of the nine components of the AHEI diet score and intensity of physical activity are shown in supplementary appendix eTables 4 and 5 (available online only). Briefly, the decline in LDL-cholesterol change was significantly associated with an increase in the ratio of white to red meat consumption (p < 0.001), the ratio of polyunsaturated to saturated fatty acids (p < 0.001), an increase in fruit consumption (p = 0.04) and a decrease in trans fats (p = 0.04). Decreases in both moderate and vigorous physical activity were associated with a smaller decrease in LDL-cholesterol.

In sensitivity analyses, we examined the role of BMI by adding the following covariates to model 3: change in BMI and the interaction term between change in BMI and BMI at baseline. The results remained largely unchanged. Similarly, when the variable ‘presence of a long-standing illness at baseline’ was replaced by the variables ‘presence of at least one non-fatal CHD event at baseline’ and ‘presence of diabetes mellitus at baseline’, respectively, in model 5, the results were much the same (data not shown).

Multivariate analyses of changes in other lipid fractions are provided in supplementary appendix, eTable 6 (available online only). An increase in physical activity was associated with a 0.05 mmol/l greater increase in HDL-cholesterol compared with those who had a stable level of physical activity. Participants whose BMI increased over the follow-up showed a 0.01 mmol/l decrease in HDL-cholesterol and a 0.27 mmol/l decrease in triglyceride concentrations.

AHEI, alternate healthy eating index; BMI, body mass index; HDL, high-density lipoprotein; LDL, low-density lipoprotein.
relative importance of medications, diet and physical activity in explaining LDL-cholesterol trends

The baseline model for this analysis, including sex, ethnicity, duration of follow-up and baseline measures of age, education, BMI and long-standing illness as covariates, explained 11.6% of the variability in the change in LDL-cholesterol. Adding lipid-lowering drugs to this model increased the coefficient of determination ($R^2$) by 29.4%. AHEI diet score and physical activity, when added into the baseline model, explained only 0.5% and 0.3% of the variability in the change in LDL-cholesterol concentrations, respectively. Each predictor had an independent effect in the mutually adjusted model. (see supplementary eTable 7, available online only).

**Estimated population-level benefits of lipid-lowering drugs and improved lifestyle**

Based on model 3 estimates, if all 858 participants with prevalent CHD or diabetes or a high risk of CVD death at baseline had been on lipid-lowering medication, as suggested in the European guidelines, then the decline in LDL-cholesterol would have been 2.77 mmol/l greater than the observed value (table 4). If all 3457 participants who did not have an optimal diet (AHEI score <60) had improved their diet, the corresponding additional decline in LDL-cholesterol would have been 0.08 mmol/l. The adoption of a more physically active lifestyle by the 2190 participants who undertook less than 2.5 h of moderate or vigorous activities per week would have produced an additional decline in LDL-cholesterol of 0.11 mmol/l. These estimations applied to the total cohort ($n=4469$) suggest that successful implementation of lipid-lowering therapy and change in lifestyle would each reduce LDL-cholesterol levels by 0.90 to 1.07 mmol/l (table 4).

*Here intervention stands for use of a lipid-lowering drug among those needing such a treatment according to the European guidelines, improving diet among those with an AHEI score less than 60, or increasing the duration of physical activity among those with less than 2.5 h/week. 1 SD increase in the AHEI score is 0.8 point and 1 SD increase in physical activity is 17 min/week.
† Decline in LDL-cholesterol estimated for participants who met the criteria for intervention based on effects shown in table 3, model 3.
‡ Participants with cardiovascular disease risk score of 5% or greater or prevalent coronary heart disease or diabetes at baseline, or lipid-lowering medication at baseline or follow-up.
§ Participants with an AHEI score of less than 60 at baseline.
¶ Participants with physical activity for less than 2.5 h/week at baseline.
* AHEI, alternate healthy eating index; LDL, low-density lipoprotein.

### DISCUSSION

We found an overall decrease in the LDL-cholesterol concentration in the Whitehall II cohort of civil servants over 11 years of follow-up. The degree of decline was associated with an increased use of lipid-lowering drugs, improvements in diet—especially the ratio of white to red meat consumption and the ratio of polyunsaturated to saturated fatty acids intake—and an increase in physical activity. In this population, the contribution of changes in lifestyle and physical activity were modest compared with pharmacological treatment among individuals at high risk of CVD. However, a successful implementation of lipid-lowering drug treatment for the relatively small group of high-risk individuals and a favourable change in diet and physical activity in the large group of people with a non-optimal lifestyle were estimated to result in largely similar declines in LDL-cholesterol in the total cohort. These findings support the use of multifaceted intervention strategies for prevention.

In many previous studies, a decrease in the LDL-cholesterol concentration has been assessed by comparing cross-sectional surveys repeated over time: in the INTERGENE and GÖT—MONICA study (1985, 1990, 1995 and 2002), in the French MONICA study (1996 and 2007), in the studies conducted in Catalonia, Spain (1992 and 2003), and in Girona, Spain (1995, 2000 and 2005). This design captures time trends but, unlike the prospective cohort design employed in the present study, does not allow an estimation of within-subject changes in LDL-cholesterol, or in their predictors.

Our study confirms the findings of the few previous cohort studies on changes in total or LDL-cholesterol among middle-aged individuals. In an Australian population-based cohort study, Buyken et al. reported a decrease of 0.7 mmol/l in LDL-cholesterol between 1992 and 2004, comparable with the 0.9 mmol/l decrease in our study. Two other cohort studies, the New Zealand Workforce Diabetes Survey and the American Physicians’ Health Study, also reported a decline in LDL-cholesterol from 1988 to 1997 and from 1982 to 1997, respectively. In the Framingham Heart Study, there was a slight increase in LDL-cholesterol over time, but these analyses did not include individuals on lipid-lowering or hormone replacement therapies, or those with prevalent CVD. Randomised trials have shown lipid-lowering drugs, diet modification and endurance exercise training to be effective in lowering LDL-cholesterol concentrations. The present results, obtained from an observational study, add to the knowledge from randomised controlled trials in which the effect size is dependent on specific interventions.

There are a few caveats to the results reported here. First, total cholesterol and triglycerides were not measured using the same enzymatic methods at both study phases; but HDL-cholesterol was assessed using the dextran sulphate—magnesium precipitation method at baseline and the direct homogeneous method at follow-up. These protocol changes might have affected the estimation of absolute LDL levels. However, this is an unlikely source of major bias because both methods have been validated and certified by the Cholesterol Reference Method Laboratory Network at the Centers for Disease Control and Prevention. and agreement between the methods is high, with a correlation coefficient of 0.98, slope 0.98 and mean bias 0.05 mmol/l. If the level of HDL-cholesterol was ‘overestimated’ by 0.05 mmol/l at follow-up in the present study, the method-related decrease in LDL-cholesterol between baseline and follow-up would have been approximately 0.06 mmol/l, which is small compared with the mean observed decrease of 0.86 mmol/l. Furthermore, bias resulting from the change in the method of assessing HDL-cholesterol is likely to be independent of the measurement of the predictors and thus should not unduly bias our findings on relative differences in changes in LDL-cholesterol between subgroups.

Second, physical activity and, to a greater extent, dietary intake, are difficult to measure accurately; whereas it is likely that the use of lipid-lowering drugs is recalled with greater precision. We may therefore have underestimated the effects of diet and physical activity on LDL-cholesterol decline. Furthermore, it is possible that we underestimated the contribution of diet because our analysis did not fully capture effects arising from externally driven secular changes in dietary patterns. For example, recommendations from the National Institute for Health and Clinical Excellence encourage manufacturers, caterers and producers to reduce the amount of saturated and trans fatty acids in all food products and replace them, if needed, by polyunsaturated and monounsaturated fatty acids. Such guidance, if successful in reducing ‘bad’ cholesterol in marketed foods, could, potentially, have a notable impact on the number of cardiovascular events at the population level, as is clear from the results from the recent meta-analysis of randomised controlled trials.

Third, regression towards the mean is a potential source of bias in observational studies with repeat outcome measures. Regression to the mean arises from random errors in measurement and should be relatively independent of the use of lipid-lowering drugs or lifestyle. In the present study, these factors remained important predictors of reduced LDL levels in...

Decline in low-density lipoprotein cholesterol concentration: lipid-lowering drugs, diet, or physical activity? Evidence from the Whitehall II study
