Methods 427 subjects with a wide range of health and disease were divided into derivation (n = 214) and validation (n = 213) cohorts (Table 1 for patient characteristics). All subjects underwent T1 mapping with ShMOLLI at 1.5 Tesla for ECV quantification. Venous blood for Hct was obtained prior to scanning with 44 patients having a repeat Hct within 6 h.

ECV was calculated as: $ECV = (\Delta[1/T1_{myo}] / \Delta[1/T1_{blood}]) * [1 - \text{haematocrit}]$.

Synthetic Hct was approximated from the linear relationship between Hct and native $T1_{blood}$ and used to calculate *synthetic* ECV. Histological validation was performed on 18 patients with severe aortic stenosis (age 71 ± 10 years, 78% male). ECV was compared with collagen volume fraction from intra-operative biopsies taken during surgical valve replacement.

Results In the derivation cohort, native $T1_{blood}$ and Hct showed a linear relationship ($R^2=0.45$; $p < 0.001$, Figure 1). This was used to derive *synthetic* Hct = $0.88 - (T1_{blood}/3240)$. *Synthetic* ECV correlated well with ECV ($R^2 = 0.99$; $p < 0.001$). These results were maintained in the validation cohort. Test:retest variability of haematocrit was higher than expected (n = 44, variability 10% with Hct:Hct $R^2 = 0.86$). On histological validation, *synthetic* and conventional ECV both correlated well with collagen volume fraction ($R^2 = 0.61$ and 0.69 , $p < 0.001$).

Conclusion *Synthetic* ECV allows instantaneous non-invasive quantification of the myocardial extracellular space without blood sampling. Inline application of *synthetic* ECV may be an attractive alternative in clinical practice.

Abstract 29 Figure 1 Correlation between T1 blood and haematocrit. In the derivation cohort (n = 214), native T1 blood and hematocrit (Hct) showed a linear relationship ($R^2 = 0.45$; $p < 0.001$). This was used to derive *synthetic* Hct = $0.88 - (T1_{blood}/3240)$.

Aim To determine the ability of whole body magnetic resonance angiography (WB-MRA) to measure global atheroma burden progression.

Methods 50 consecutive patients with symptomatic peripheral arterial disease referred for clinical MRA were recruited. WB-MRA was performed at baseline, 6 months and 3 years. WB-MRA data was analysed by dividing the vasculature into 31 anatomical arterial segments. Each segment was scored according to degree of luminal narrowing: 0=normal, 1 = <50%, 2 = 50–70%, 3 = 71–99%, 4 = vessel occlusion. From this a standardised atheroma score (SAS) was calculated with a maximum score of 100 and minimum score of 0. Progression was assessed with repeat measure ANOVA.

Results 36 patients were scanned at 0 and 6 months, with 26 patients scanned at the three year follow up. Only those who completed all 3 visits were included in the final analysis. At 3 years, n = 18 demonstrated atheroma progression while n = 8 showed stable or improved disease. Those with no progression had significantly lower baseline SAS, and were more likely to be on statin therapy ($p < 0.05$ for both). Baseline SAS was 15.7 ± 10.3 at baseline with no progression at 6 months ($SAS=16.4 \pm 10.5$, $p = 0.67$). At 3 years there was significant progression in atheroma ($SAS = 17.7 \pm 11.5$, $p = 0.01$) (Figure 1). On multiple linear regression, age (β 0.14 $p = 0.014$), pulse pressure (β -0.12 $p = 0.005$) and ankle-brachial pressure index (β -7.7 $p = 0.036$) were independently associated with the rate of progression.

Abstract 30 Figure 1 Comparison of atheroma score at baseline, 6 months and 3 years. Visit 1 = Baseline, Visit 2 = 6months, Visit 3 = 3 years. T-bars represent 95% confidence intervals.

Conclusion Whole body contrast enhanced MRA can quantify and monitor atherosclerosis progression at 3 year follow-up even in a small cohort.
