## ABSTRACT

Regional myocardial ischaemia is commonly expressed as exertional angina in patients with stable coronary artery disease (CAD). It also associates with prognosis, risk tending to increase with the severity of ischaemia. The validity of myocardial ischaemia as a surrogate for adverse clinical outcomes, however, has not been well established. Thus, in cohort studies, ischaemia testing has failed to influence rates of myocardial infarction and coronary death. Moreover, in clinical studies, pharmacological and interventional treatments that are effective in correcting ischaemia have rarely been shown to reduce cardiovascular (CV) risk. This contrasts with statins and other anti-inflammatory drugs that have no direct effect on ischaemia but improve CV outcomes by modifying the atherothrombotic disease process. Despite this, and with little evidence of patient benefit, stress testing is commonly used during the follow-up of patients with stable CAD when the demonstration of ischaemic change may be seen as a target for treatment, independently of symptomatic status. Substitution of a symptom-driven management strategy has the potential to reduce rates of non-invasive stress testing, unnecessary downstream revascularisation procedures and use of valuable resources in patients with stable CAD without adverse consequences for CV risk.

## INTRODUCTION

In patients with coronary artery disease (CAD), the burden of ischaemia is related to the extent and functional significance of luminal obstruction, as influenced by lesion characteristics, collateral development and other factors affecting the balance of myocardial oxygen supply and demand. Ischaemia is an important determinant of symptoms, usually expressed as angina in patients with stable CAD, but the relationship is unpredictable, and 'silent' myocardial ischaemia can often be demonstrated in patients with CAD who experience no angina.<sup>1</sup> Alternatively, angina may occur in patients with angiographically unobstructed coronary arteries.<sup>2</sup>

Detection of ischaemia non-invasively relies on functional cardiac testing during exertional or pharmacological stress. Functional responses to ischaemia are typically regional in distribution and resolve with relief of the stress. They include electrocardiographic ST segment and T wave changes, echocardiographic left ventricular wall motion abnormalities and perfusion defects detected by single-photon emission computed tomography (SPECT) or cardiac magnetic resonance (cMR) perfusion imaging. Alternatively, fractional flow reserve (FFR) may be used to assess the functional

significance of coronary stenoses.<sup>3</sup> FFR is usually measured during invasive coronary angiography, but less invasive methods are now available using analysis of quantitative flow ratio or CT coronary angiography (CTCA).<sup>4,5</sup>

Inducible ischaemia during stress testing is widely used as a surrogate of cardiovascular (CV) risk in patients with stable CAD and may reduce thresholds for revascularisation in symptomatic and asymptomatic subgroups according to international guideline recommendations.<sup>6,7</sup> Inducible ischaemia has also been used as a surrogate endpoint in clinical outcome trials.<sup>8</sup> However, its validity as a surrogate of CV risk merits further scrutiny. In this article, we examine whether or not myocardial ischaemia meets the following key criteria for surrogacy of adverse clinical outcomes in patients with stable CAD: (1) an association with major adverse cardiac events, (2) a place on the causal pathway and (3) responsiveness of cardiac events to treatment-related changes in inducible ischaemia.<sup>8-10</sup>

## Ischaemia and the risk of major adverse cardiac events

Cohort studies in patients with known or suspected CAD have reported associations between myocardial ischaemia and major adverse cardiac events. In a 1998 study of 5183 patients undergoing stress SPECT,<sup>11</sup> the risk of cardiac death or myocardial infarction during follow-up for 2 years was low in patients with normal scans but increased incrementally with worsening scan abnormalities. A 2012 study of stress SPECT confirmed these findings by showing that the risk of acute coronary syndromes during 5–25 years of follow-up of 1287 asymptomatic siblings of people with premature CAD showed a dose–response relationship with the severity of ischaemia.<sup>12</sup> A 2013 meta-analysis of 19 studies of stress cMR involving a total of 11 636 patients followed up for an average of 32 months showed that patients with ischaemia had a higher incidence of myocardial infarction (MI) (OR 7.7;  $p < 0.0001$ ), CV death (OR 7.0;  $p < 0.0001$ ) and the combined endpoint (OR 6.5;  $p < 0.0001$ ) compared with those with a negative study.<sup>13</sup>

In the prospective 'Heart and Soul' study of 1024 patients undergoing stress echocardiography, inducible ischaemia was an independent predictor of both CV (RR 2.28 (95% CI 1.44 to 3.61)) and non-CV (RR 1.83 (95% CI 1.24 to 2.70)) mortality during follow-up for 10 years.<sup>14</sup> The larger The Prospective Observational Longitudinal Registry of Patients With Stable Coronary Artery Disease (CLARIFY)

**To cite:** Timmis A, Raharja A, Archbold RA, et al. *Heart* 2018;**104**:1733–1738.

**Figure 1** (A) Coronary angiogram in a patient who presented with non-ST elevation myocardial infarction showing severe disease proximally in the LAD coronary artery with collateralisation of an occluded RCA. Coronary artery bypass surgery with grafts to the LAD and RCA produced complete symptomatic relief. (B) Eighteen months later, the patient presented with unstable angina. Coronary angiography confirmed patency of both grafts, but the obtuse marginal branch of the circumflex coronary artery had occluded (arrow) due to rupture of subcritical plaque at its origin. LAD, left anterior descending; RCA, right coronary artery.

registry of >20 000 patients with stable CAD who underwent non-invasive ischaemia testing (stress ECG, stress echocardiogram or SPECT) also found association between ischaemia and CV endpoints but only for patients with angina (HR 1.75 (95% CI 1.34 to 2.29)) and patients with silent ischaemia showing no excess risk compared with patients with neither angina nor ischaemia.<sup>15</sup>

### Ischaemia and causal pathways of CV risk

The association of inducible ischaemia with CV endpoints does not confirm its status as a surrogate if it does not lie on the causal pathway for these endpoints.<sup>8</sup> Evidence questioning a causal role for ischaemia includes the clinical observation that more than half of patients presenting for the first time with myocardial infarction have no prior angina.<sup>16 17</sup> Similarly, in stable CAD populations including CLARIFY and cohorts attending chest pain clinics, a significant proportion of cardiac events occur in patients without angina or demonstrable ischaemia, no doubt reflecting rupture of non-obstructive plaque that had not been identified by functional testing.<sup>15 18</sup> These clinical observations suggesting that ischaemia may not be a necessary prerequisite for adverse coronary events are borne out by angiographic studies which show that non-obstructive coronary plaques are as likely to provide a substrate for myocardial infarction as more severely obstructive plaques (figure 1A and B).<sup>19 20</sup> This in turn is consistent with pathophysiological mechanisms of acute coronary syndromes in which it is not the degree of coronary luminal obstruction but the vulnerability of the plaque, defined by factors including cap thickness, lipid pool dimensions and inflammatory infiltrates, that determines the risk of plaque rupture and thrombotic coronary occlusion.<sup>21</sup> Plaque vulnerability may itself induce endothelial dysfunction and myocardial ischaemia, but this does not put ischaemia on the causal pathway without evidence that its treatment has plaque stabilising effects.<sup>22</sup> These clinical, angiographic and pathophysiological observations argue against ischaemia lying on the causal pathway for CV events and question its

biological plausibility as a valid surrogate for acute MI (AMI) and coronary death in patients with stable CAD (figure 2).

### Diagnostic stress testing and CV outcomes

A crucial requirement for validation of ischaemia as a surrogate endpoint is that its treatment should cause parallel reduction in the risk of adverse CV outcomes.<sup>8–10</sup> This would be unlikely if, as argued above, ischaemia does not lie on the causal pathway for these outcomes. Randomised trials of non-invasive ischaemia testing and its contribution to risk reduction in patients with suspected or established CAD are lacking, but indirect evidence from cohort studies tends to confirm that coronary event rates are unaffected by these investigations. In a registry analysis of nearly 250 000 patients who had undergone percutaneous coronary intervention (PCI), top quartile hospitals for rates of non-invasive stress testing performed more repeat revascularisation procedures but had almost identical adjusted risk of myocardial infarction and death compared with hospitals in the bottom quartile.<sup>23</sup> Findings were similar in a study of more than half a million patients with chest pain in 224 US hospitals who underwent cardiac stress imaging.<sup>24</sup> Again, hospitals with higher imaging rates did not have substantially different rates of therapeutic interventions or lower readmission rates for AMI but were more likely to admit patients and perform angiography. The authors of both studies questioned whether increased testing is a marker for improved quality of post-PCI care or simply increased healthcare utilisation.

### Interventions targeted at ischaemia and CV outcomes

More direct evidence about the validity of inducible ischaemia as a surrogate for CV endpoints comes from observations of treatment effects.

### Medical therapy

For patients with angina, the benefits of targeting ischaemia are well documented and underpin the clinical application of all

**Figure 2** The causal pathway for AMI and coronary death (red arrows). This simplified diagram identifies inducible ischaemia as a consequence of coronary artery disease but shows that if it does not lie on the causal pathway for coronary events, then modification of ischaemia will fail to influence cardiovascular risk. AMI, acute myocardial infarction; PCI, percutaneous coronary intervention.

the commonly used antianginal drugs including nitrates, beta-blockers, ivabradine and calcium channel blockers. Yet, despite the benefits of these drugs for reducing myocardial ischaemia and correcting symptoms in patients with stable CAD, there is no evidence that they protect against CV events. In The Study Assessing the Morbidity–Mortality Benefits of the If Inhibitor ivabradine in Patients with Coronary Artery Disease, for example, there was no outcome benefit for the group randomised to ivabradine despite significant reduction in angina frequency compared with the placebo group.<sup>25</sup> In the Reduction of Atherothrombosis for Continued Health (REACH) registry too, the risk of composite CV events was comparable in propensity matched cohorts stratified by beta-blocker therapy, although the effects of treatment on symptoms or inducible ischaemia were not recorded in this study.<sup>26</sup>

### Revascularisation

PCI can further augment ischaemia reduction in patients receiving medical therapy (MT), but convincing evidence that it protects against CV events in patients with stable CAD is lacking. Thus, in the landmark Clinical Outcomes Utilizing Revascularization and Aggressive Drug Evaluation trial, the addition of PCI to optimal MT (OMT) was associated with more effective reduction of ischaemia yet failed to reduce event rates compared with OMT alone.<sup>27</sup> Patients who exhibited  $\geq 5\%$  reduction in ischaemic myocardium had better outcomes compared with patients with a less pronounced response to treatment, but the difference disappeared in risk-adjusted analysis.<sup>28</sup> Similarly, in Bypass Angioplasty Revascularization Investigation 2 Diabetes, revascularisation was associated with significantly less ischaemic myocardium at 1 year compared with MT, yet outcomes were similar, and there was no significant difference between the groups in rates of death and major CV events.<sup>29</sup>

Dissociation between ischaemia reduction in response to revascularisation and CV outcomes in stable CAD is variably borne out by observational data. In a large study of >10 000 patients who underwent exercise or adenosine stress myocardial perfusion scintigraphy during the 1990s,  $\sim 7\%$  underwent revascularisation by PCI or coronary artery bypass grafting (CABG), whereas the remainder continued on medical treatment.<sup>30</sup> Mortality was higher for revascularisation compared with medical treatment, perhaps reflecting biased selection of sicker patients, and only after multiple comparisons between these treatment strategies for subgroups defined by the extent of ischaemic myocardium

could a mortality benefit be demonstrated for revascularisation among patients with >20% ischaemic myocardium. This study has been presented as supporting a strategy of revascularisation for reducing ischaemia and protecting against cardiac events despite a substantial overall survival benefit for medically treated patients. Of note was the choice of CABG in the majority of patients with >20% ischaemic myocardium which may have contributed to the mortality benefit, less through relief of ischaemia than protection against the consequences of plaque events in the proximal coronary circulation (see below). Similarly, inconclusive was an analysis of nearly 40 000 patients with stable CAD from the REACH registry in which the risk of CV death at 36 months of median follow-up was lower in patients with previous PCI but higher in patients with previous CABG compared with patients managed medically.<sup>31</sup> Meanwhile, a propensity matched study of MT versus revascularisation in patients with silent ischaemia on myocardial perfusion scintigraphy had found almost identical all-cause mortality in the two groups during follow-up.<sup>32</sup>

Evidence from randomised trials for prognostic benefit of CABG in stable CAD is more robust, and a meta-analysis showed improved survival for CABG compared with medical treatment for patients with left main and multivessel disease, particularly those with left ventricular dysfunction.<sup>33</sup> The trials included in this meta-analysis were conducted over 40 years ago, but, although relevance to contemporary practice may be questionable, their findings appear to be borne out by the recent Surgical Treatment for Ischemic Heart Failure trial, in which a 10-year follow-up of 1212 patients with ischaemic cardiomyopathy showed reduced rates of death from any cause for patients randomised to CABG compared with medical treatment.<sup>34</sup> The outcome, however, was independent of inducible ischaemia at baseline, making bypass of vulnerable plaque in the proximal coronary circulation a more likely mechanism of benefit than reduction in ischaemia.<sup>35–36</sup> PCI offers no protection against plaque events, despite its effectiveness for correcting ischaemia, and this may account for its association with less favourable outcomes and reduced cost-effectiveness compared with CABG in studies that have recruited patients with high ischaemic burden.<sup>37–39</sup>

The treatment data summarised above do not provide a strong case for validation of ischaemia as a surrogate CV endpoint, but they have been challenged by the Fractional Flow Reserve Versus Angiography for Multivessel Evaluation 2 (FAME-2) trial.<sup>40</sup> In FAME-2, 888 patients with stable CAD were randomised to

**Table 1** FAME-2

	PCI+MT (n=447)	MT alone (n=441)	P value
	n (%)	n (%)	
MACEs	45 (10.1)	97 (22.0)	<0.001
Death	12 (2.7)	16 (3.6)	0.43
MI	28 (6.3)	34 (7.7)	0.41
Urgent revascularisation	19 (4.3)	76 (17.2)	<0.001
Death or MI	37 (8.3)	46 (10.4)	0.28

MACEs at a 3-year follow-up in groups randomised to PCI plus MT or to MT alone. FAME-2, Fractional Flow Reserve Versus Angiography for Multivessel Evaluation 2; MACE, major adverse cardiovascular event; MI, myocardial infarction; MT, medical therapy; PCI, percutaneous coronary intervention.

MT or MT plus FFR-guided PCI in which only functionally significant lesions with the potential to cause ischaemia were stented. After 3 years, major adverse cardiac events were significantly less frequent in the PCI group compared with the MT group (10.1% vs 22.0%;  $p < 0.001$ ). The outcome advantage for the PCI group was largely driven by a lower rate of urgent revascularisation (4.3% vs 17.2%;  $p < 0.001$ ) with no significant difference in rates of death or myocardial infarction (table 1). The extent to which the unblinded treatment allocation in FAME-2 biased the outcome is speculative, but knowledge that the MT group had at least one functionally significant coronary stenosis that had been left unstented might plausibly have reduced thresholds for hospital admission and intervention in patients presenting with recurrent chest pain, resulting in the observed increase in the rate of urgent revascularisation compared with the FFR-guided PCI group. In terms of hard endpoints, however, FAME-2 was a negative trial and when included in a meta-analysis of five randomised trials investigators concluded that in patients with stable CAD and objectively documented myocardial ischaemia, PCI with MT was not associated with a reduction in death or non-fatal myocardial infarction compared with MT alone.<sup>41</sup>

### CLINICAL CONSIDERATIONS

The data support a unifying hypothesis of ischaemia as a marker of atheroma burden that drives risk through predisposition to plaque events. Interventions that modify ischaemia without affecting plaque stability, therefore, may improve symptoms but are unlikely to have any effect on the risk of myocardial infarction or coronary death (figure 2). This accounts for the failure of antianginal drugs and PCI to reduce CV risk and for the success of statins and anti-inflammatory drugs which target the atherothrombotic process but have no direct anti-ischaemic effects.<sup>42 43</sup> Clinically, the evidence favours a symptom-driven management approach in which treatment decisions are based more on chest pain characteristics than the results of functional stress testing. Symptom-driven management recognises that treatment of ischaemia may offer no protection against myocardial infarction or coronary death but is usually effective for relieving symptoms although the Objective Randomised Blinded

Investigation with optimal medical Therapy of Angioplasty in stable angina (ORBITA) trial has cast interesting light on mechanisms contributing to the symptomatic benefit.<sup>44</sup> This questions the logic of stress testing in asymptomatic patients who may have little to gain prognostically and nothing to gain symptomatically. Stress testing continues to have a role for the diagnosis of coronary disease, yet there is considerable overuse with failure to meet appropriateness criteria in up to 70% of tests, resulting in increased rates of downstream angiography without influencing the risk of myocardial infarction or coronary death.<sup>45 46</sup> England's National Institute for Health and Care Excellence has recommended a move away from diagnostic stress testing in favour of anatomical testing with CTCA in patients with suspected angina, but whether its enhanced diagnostic value will be realised in practice awaits confirmation.<sup>47</sup> Preliminary data are favourable,<sup>48</sup> and the potential added value of CTCA for identification of vulnerable plaque in patients without inducible ischaemia, if fulfilled, may help identify high risk subgroups invisible to stress testing.<sup>49</sup> Meanwhile, contemporary healthcare systems face increasing resource constraints with stable CAD contributing importantly to costs.<sup>50</sup> Addressing the overuse of stress testing represents an important opportunity for reducing costs without adversely affecting patient outcomes.

### CONCLUSION

The balance of available evidence weighs against inducible myocardial ischaemia as a valid surrogate for CV endpoints and a therapeutic target for risk reduction in patients with stable CAD. It shows that ischaemia associates with adverse CV outcomes but does not lie on the causal pathway, and treatment to reduce ischaemic burden rarely, therefore, protects against myocardial infarction or coronary mortality. In this respect, ischaemia shows similarity with other failed surrogates, such as homocysteine and high-density lipoprotein cholesterol, both of which show association with CV outcomes that have proved unresponsive to interventions that modify plasma concentrations of these risk factors.<sup>51 52</sup> This contrasts with established surrogates of CV risk, such as low-density lipoprotein cholesterol, treatment of which produces salutary protection against myocardial infarction and coronary death (table 2).<sup>42</sup>

Consistent though the data are in portraying inducible myocardial ischaemia as a failed surrogate for CV endpoints, they cannot be considered confirmatory. The Hachamovitch study remains influential based on its finding of improved outcomes with revascularisation (predominantly CABG) in a severely ischaemic subgroup,<sup>11</sup> and FAME-2 concluded that FFR-guided coronary stenting plus best available MT was superior to MT alone for reducing rates of composite CV outcomes, even though rates of death and myocardial infarction were unaffected.<sup>40</sup> Residual uncertainty about the role of a symptom-driven approach in the management of patients with stable CAD may be resolved by the ongoing International Study of Comparative Health Effectiveness with Medical and Invasive

**Table 2** Validation criteria for four CV biomarkers

Validation criteria	Inducible ischaemia	LDL cholesterol	HDL cholesterol	Homocysteine
1. Prognostic value: does biomarker correlate with adverse CV outcomes?	+++	+++	+++	++
2. Biological plausibility: is biomarker on the causal pathway for adverse CV outcomes?	+/-	+++	+	-
3. Treatment effects: do changes in biomarker produce similar changes in the outcome?	+/-	+++	-	-

All show strong correlation with adverse CV outcomes (myocardial infarction and coronary death), but only LDL cholesterol meets the validity criteria as a surrogate of CV risk. CV, cardiovascular; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Approaches in which recruitment of 5000–6000 patients with preserved left ventricular function (ejection fraction  $\geq 35\%$ ) and at least moderate ischaemia on non-invasive testing is almost complete.<sup>53</sup> These patients are being randomised to an invasive or conservative management strategy with follow-up for all-cause and CV mortality. Whether the invasive approach delivers improved CV outcomes as a consequence of more effective reductions in ischaemic burden is an important question that will further inform debate about management strategies in patients with stable CAD.
