ABSTRACT

Objective To evaluate the association between chocolate intake and incident clinically apparent atrial fibrillation or flutter (AF).

Methods The Danish Diet, Cancer, and Health Study is a large population-based prospective cohort study. The present study is based on 55 502 participants (26 400 men and 29 102 women) aged 50–64 years who had provided information on chocolate intake at baseline. Incident cases of AF were ascertained by linkage with nationwide registries.

Results During a median of 13.5 years there were 3346 cases of AF. Compared with chocolate intake less than once per month, the rate of AF was lower for people consuming 1–3 servings/month (hazard ratio (HR) 0.90, 95% confidence interval (CI) 0.82 to 0.98), 1 serving/week (HR 0.83, 95% CI 0.74 to 0.92), 2–6 servings/week (HR 0.80, 95% CI 0.71 to 0.91) and ≥ 1 servings/day (HR 0.84, 95% CI 0.65 to 1.09; p-linear trend <0.0001), with similar results for men and women.

Conclusions Accumulating evidence indicates that moderate chocolate intake may be inversely associated with AF risk, although residual confounding cannot be ruled out.

INTRODUCTION

Atrial fibrillation (AF) is the most common arrhythmia in clinical practice, affecting 2.7–6.1 million people in the USA and 8.8 million in the European Union.¹ AF is associated with a higher risk of stroke, heart failure, cognitive decline, dementia and mortality,² so identifying methods for preventing and identifying effective treatments for AF is of great public health importance.

Moderate consumption of cocoa and cocoa-containing foods may promote cardiovascular health due to their high content of flavanols, a subgroup of polyphenols with vasodilatory, antioxidant and anti-inflammatory benefits.^{3–4} There has been extensive research showing that moderate consumption of chocolate, particularly dark chocolate, improves markers of cardiovascular health⁵ and is associated with a lower rate of myocardial infarction,⁶ heart failure,^{7–8} composite cardiovascular adverse outcome and cardiovascular mortality.⁹ However, there is limited research on whether chocolate intake is associated with a lower rate of AF.

Recent evidence suggests that the pathophysiology of AF involves an inflammatory cascade resulting in a release of cytokines, reactive oxygen species and stimulation of fibroblast proliferation, differentiation and activation.¹⁰ Higher levels of inflammation may result in endothelial damage, increased platelet activation and increased expression of fibrinogen that leads to electrical and structural remodelling of atrial tissue and thereby increase AF risk.¹¹ Therefore, we hypothesised that the anti-inflammatory and antiplatelet benefits of cocoa may be associated with a lower rate of AF.

We aimed to evaluate whether there is an association between chocolate intake and the rate of clinically apparent AF after adjusting for relevant confounders in a large prospective cohort study of men and women enrolled in the Danish Diet, Cancer, and Health Study.

METHODS

Study population

Between December 1993 and May 1997, the prospective Danish Diet, Cancer, and Health Study invited 160 725 individuals to participate. Inclusion criteria were 50–64 years of age, residence in the greater Copenhagen or Aarhus area and no previous cancer diagnosis in the Danish National Patient Register. At enrolment, anthropometric measurements were taken and biological materials were collected at one of the study centres; information on diet and lifestyle was obtained using self-administered questionnaires including a semiquantitative food frequency questionnaire (FFQ). Using the unique personal identification number (CPR number), we linked the cohort to the Danish National Patient Register to identify primary discharge diagnoses for AF or flutter (International Classification of Diseases, 10th Revision: I48) through December 2009. The study was approved by the regional Ethical Committees on Human Studies (jr.nr. (KF) 11-037/01) and (jr.nr. (KF) 01-045/93) and the Danish Data Protection Agency. All participants gave verbal and written informed consent.

Chocolate intake

At baseline, participants completed a 192-item FFQ that was validated against two 7-day weighed diet records.^{12–13} Average intake of each food item during the last 12 months was reported in 10 categories from ‘never’ to ‘4–5 per day’. For each

participant, average daily intake was calculated using the Food Calc software V1.3 (J Lauritsen, University of Copenhagen; <http://www.ibt.ku.dk/jesper/foodcalc/>). Standard recipes and sex-specific portion sizes were applied to calculate intake in grams per day by using data from the 1995 Danish National Dietary Survey, 24-hour diet recall interviews from 3818 of the study participants¹⁴ and several cookbooks. A serving of chocolate was defined as 1 ounce, consistent with the results of a validation study¹⁵ that showed that the approximate serving size of chocolate in Swedish men is 30 g chocolate. The questionnaire did not differentiate between milk and dark chocolate, but most chocolate consumed in Denmark has a minimum of 30% cocoa solids.¹⁶

Atrial fibrillation

All citizens of Denmark have a unique personal identification number that is used in all national registries, and updated information is available on emigration, hospitalisations and death. The Danish National Patient Register includes discharge diagnoses from in-hospital patients since 1977 and additional discharge diagnoses from emergency rooms and outpatient visits since 1995.

The outcome in this study was incident clinically apparent AF and/or atrial flutter (AFL) during the study period. Diagnoses were recorded using the Eighth International Classification of Diseases (ICD-8) until the end of 1993 (AF (427.93) and AFL (427.94) in the Danish version which is equivalent to AF or AFL (427.4) in the international version). From January 1994, the ICD-10 classification was used with the diagnosis of AF and/or AFL (I.48). The validity of the combined diagnosis of AF and/or AFL is high, with a positive predictive value of 92.6% in this cohort.¹⁷ If a patient had both an emergency room visit and a hospital admission on the same date, only the in-hospital diagnosis was considered in order to avoid possible misclassification. In line with previous observational studies, the combined diagnosis of 'AF and/or AFL' was referred to as AF.

Other covariates

We obtained information on demographics and lifestyle factors using a self-administered questionnaire. Body mass index (BMI), blood pressure and total cholesterol were measured by a laboratory technician at the time of recruitment.¹⁸ We used self-reports, ICD codes and Anatomical Therapeutic Chemical (ATC) drug codes to obtain information on prevalent and incident hypertension, diabetes mellitus and cardiovascular disease (yes/no).¹⁹

Statistical analysis

Individuals were considered at risk from the date of the study questionnaire (1993–1997) until the date of first hospital admission for AF, death, emigration or end of follow-up (December 2009), whichever came first. Consistent with prior studies on chocolate intake and AF, we modelled chocolate intake using the following categories of servings of 1 ounce bars or packets of chocolate: <1/month, 1–3/month, 1/week, 2–6/week and ≥1/day. We constructed multivariable Cox proportional hazards models with age as the time scale and allowed the baseline hazard to vary by sex to calculate the hazard ratio (HR) and 95% confidence intervals (CIs) for the association between chocolate intake and the rate of AF. We chose covariates a priori²⁰ that we considered potential confounders on the basis of their association with development of AF: from the baseline data we included information on sex, BMI (kg/m²), systolic blood pressure (mm Hg), total serum cholesterol (continuous),

total calories (continuous), coffee consumption (continuous), alcohol consumption (g/day), smoking status (never, former, current) and years of education beyond elementary school (0, <3, 3–4, >4 years). We used regularly updated information on hypertension (yes/no), diabetes mellitus (yes/no) and cardiovascular disease (yes/no) using time-varying covariates. Because there was no gradient in caffeine across categories of chocolate intake and it may be a consequence of chocolate intake, we did not include caffeine consumption as a covariate. We conducted tests of the linear component of trend for increasing categories of chocolate intake by assigning the median values for each category and testing the statistical significance of the term in the multivariable model.

To test the robustness of the model, we examined whether the HRs varied by sex, history of hypertension, diabetes or cardiovascular disease by conducting likelihood ratio tests to compare models with versus without cross-product terms for categories of exposure and the potential modifier. We constructed a multivariable model further adjusted for caffeine from sources other than chocolate (coffee, tea and soft drinks) instead of adjusting for coffee consumption. Since unrecognised illness may influence chocolate consumption at baseline, we conducted a sensitivity analysis excluding the first 2 years or 5 years of follow-up.

We tested the proportional hazard assumptions using Schoenfeld residuals and interactions with the logarithm of time, and we found no significant violations after allowing the baseline hazard to vary by sex. Statistical analyses were performed using Stata V13 (Stata Corp, College Station, Texas, USA) with two-tailed tests set at $\alpha=0.05$ for statistical significance.

RESULTS

Danish Diet, Cancer, and Health Study

Among the 57 053 women and men recruited, we excluded participants for whom information was missing on chocolate intake ($n=16$), inclusion date ($n=42$) or one or more confounders ($n=477$). In addition, we excluded one participant with no FFQ, 451 participants with a previous record of AF in the Danish Registry and 564 participants who had a history of cancer at baseline (the primary outcome of the original cohort study). This resulted in a sample of 55 502 participants for these analyses. In total, 3346 incident cases of AF occurred during a median of 13.5 years of follow-up. Overall, 36% of the sample were current smokers at baseline. Participants with higher levels of chocolate intake were more likely to report higher levels of daily caloric intake, a higher proportion of calories from chocolate and a higher level of educational attainment (table 1).

Compared with chocolate intake of less than once per month, the rate of AF was lower for people consuming 1–3 servings/month (HR 0.90, 95% CI 0.82 to 0.98), 1 serving/week (HR 0.83, 95% CI 0.74 to 0.92), 2–6 servings/week (HR 0.80, 95% CI 0.71 to 0.91) and ≥1 servings/day (HR 0.84, 95% CI 0.65 to 1.09; p -linear trend <0.0001; figure 1).

In analyses stratified by sex, the incidence rate of AF was lower among women than men at each level of chocolate intake, but the lower risk of AF with higher levels of chocolate intake was apparent for both men (p -linear trend=0.002) and women (p -linear trend=0.017) in the multivariable models accounting for several potential confounders (figure 1). Among women, the strongest inverse association was seen for one serving of chocolate per week (HR 0.79, 95% CI 0.66 to 0.95) and, among men, the strongest inverse association was seen for 2–6 servings of chocolate per week (HR 0.77, 95% CI 0.67 to 0.90).

Table 1 Baseline characteristics of the subjects in the Danish Diet, Cancer, and Health Study according to frequency of chocolate intake

Values shown are mean±standard deviation, median (interquartile range) or n (%).
 *Caffeine from sources other than chocolate (coffee, tea and soft drinks).
 IQR, interquartile range.

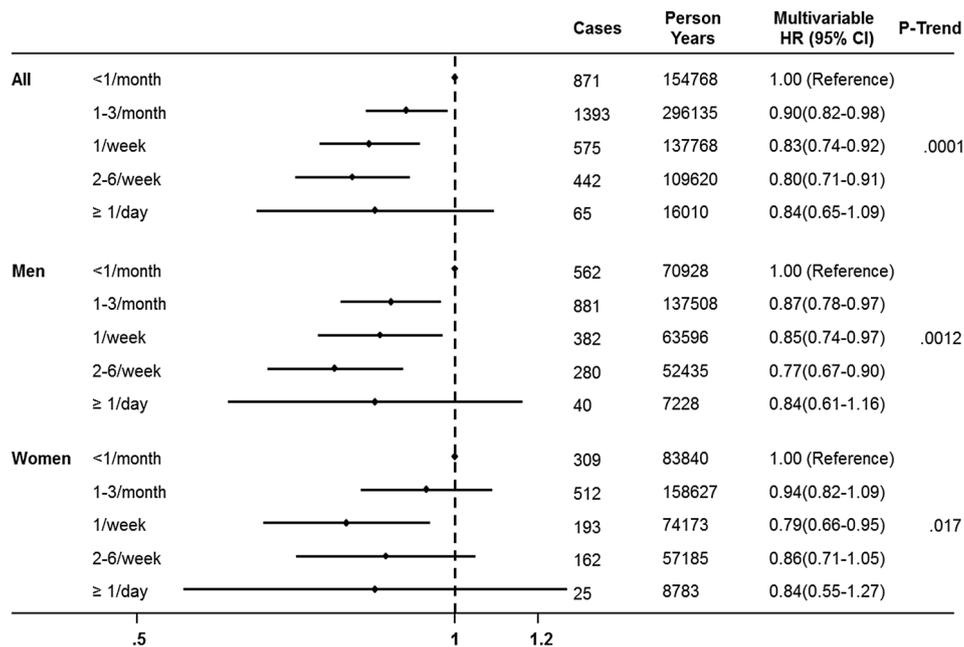

Figure 1 Multivariable hazard ratios (HRs) and 95% confidence intervals (CIs) according to frequency of chocolate intake in the Danish Diet, Cancer, and Health Study. p trend is the value for linear component of trend. Age was the time scale in the Cox models and we adjusted for total calories, sex, BMI, systolic blood pressure (mm Hg), total serum cholesterol (continuous), coffee consumption (continuous), alcohol consumption (g/day), smoking status (never, former, current), years of education beyond elementary school (0, <3, 3–4, >4 years), hypertension (yes/no), diabetes mellitus (yes/no) and cardiovascular disease (yes/no).

In sensitivity analyses to test the robustness of the model, the results were similar across levels of history of hypertension (p-interaction=0.69) and cardiovascular disease (p-interaction=0.74). Although the results were different for the 284 individuals with diabetes (p-interaction=0.01), this was driven by the small number of individuals with diabetes who reported high levels of chocolate intake. The results were almost identical when we adjusted for caffeine from sources other than chocolate (coffee, tea and soft drinks) instead of adjusting for coffee consumption.

The results were not meaningfully altered in analyses excluding the first 2 or 5 years of follow-up, suggesting that the results are not likely to be due to the potential impact of reverse causation.

DISCUSSION

In the Danish Diet, Cancer, and Health Study, higher levels of chocolate intake were associated with an 11–20% lower rate of clinically apparent AF among men and women. We adjusted for total caloric intake since, a priori, we anticipated that it would be associated with the risk of AF and may confound the association. Since chocolate only contributes a small proportion of total calories, the results of the model do not imply that higher levels of chocolate intake results in substantially lower intake of other foods.

Two prior prospective cohort studies examined the association between chocolate intake and the rate of AF. Our results are consistent with results from the Women's Health Study which reported that moderate chocolate intake was associated with a 1–14% lower rate of self-reported AF, although the estimates for each category of intake did not reach statistical significance.²¹ Conversely, results from the Physicians' Health Study of men did not find evidence of an association between chocolate intake and self-reported AF, and the point estimates suggested that higher levels of chocolate intake may be associated with a 4–14% higher rate of self-reported AF, although the results did not reach statistical significance.²² In the current study, the lower rate of AF with higher levels of chocolate intake was apparent for both men and women.

There are several potential sources of heterogeneity across the studies. In this study we identified cases of clinically apparent AF as a primary cause in the National Registry whereas the prior two studies assessed the risk of self-reported AF verified in medical records. Based on the two prior studies, it may appear that the association varies by sex, but the results were similar for men and women enrolled in the Danish Diet, Cancer, and Health Study. It is possible that the accuracy of self-reported chocolate intake or AF symptoms was different for the sample of women recruited from the general population in the Women's Health Study compared with reporting by the physicians enrolled in the Physicians' Health Study, but it is unclear how this would result in a systematic bias. It is also possible that the presence of potential confounding by factors related to chocolate intake and AF risk is different for the two samples, but this too is not clear or verifiable from the available data. Since chocolate in Europe has a higher cocoa content than chocolate in the USA,¹⁶ it is possible that our results were stronger than the results of the two US studies due to higher intake of potentially protective components of chocolate per serving.

Recent evidence suggests that an inflammatory cascade resulting in leucocyte activation may lead to generation of reactive oxygen species, proliferation of fibroblasts and adverse turnover in matrix proteins. This may result in electrical and structural atrial remodelling and lead to the incidence of AF. The

antioxidant, anti-inflammatory and antiplatelet properties of cocoa may improve endothelial function, lipid levels, blood pressure and insulin resistance²³ and decrease fibrosis and downstream electrical and structural remodelling of atrial tissue.^{10 11} In addition, a typical 100 calorie serving of dark chocolate contains 36 mg of magnesium, which has hypotensive and antiarrhythmic effects.²⁴ These properties may explain the lower cardiovascular risk associated with moderate chocolate intake.

The higher flavonoid content of dark chocolate compared with milk chocolate may yield greater cardiovascular benefits. A randomised trial found that, compared with milk chocolate, dark chocolate may have a higher caloric content but it also promotes greater satiety and lowers the desire to eat something sweet, resulting in an overall lower caloric intake.²⁵ In addition, flavanol content and total antioxidant capacity in plasma may be lower if cocoa is consumed with milk or if cocoa is ingested as milk chocolate.²⁶ Furthermore, cocoa is usually consumed in high calorie products that use fat and sugar, and modern manufacturing of chocolate may result in losses of more than 80% of the original flavonoids from the cocoa beans.²⁷ Therefore, it may be advantageous to find ways to consume cocoa in forms other than chocolate bars. The ongoing Cocoa Supplement and Multivitamin Outcomes Study is a large randomised trial testing the effect of a concentrated cocoa extract on cardiovascular risk, and may provide insight on the efficacy and feasibility of ingesting cocoa in this form.

There are some limitations to our study that warrant discussion. Although we had extensive data on diet, lifestyle and comorbidities, we cannot preclude the possibility of residual or unmeasured confounding. For instance, data were not available on renal disease and sleep apnoea. However, after adjusting for age, smoking status and other potential confounders, the association was somewhat attenuated but remained statistically significant. We did not have information on the type of chocolate or cocoa concentration. However, most of the chocolate consumed in Denmark is milk chocolate. In the European Union, milk chocolate must contain a minimum of 30% cocoa solids and dark chocolate must contain a minimum of 43% cocoa solids; the corresponding proportions in the USA are 10% and 35%.¹⁶ Despite the fact that most of the chocolate consumed in our sample probably contained relatively low concentrations of the potentially protective ingredients, we still observed a robust statistically significant association, suggesting that our findings may underestimate the protective effects of dark chocolate.

As with any study using self-reported exposure information, there is a concern of poor recall. However, our FFQ was validated in a study comparing two 7-day weighted diet records.¹³ Furthermore, if the misclassification of chocolate intake was unrelated to AF incidence, our results would likely be an underestimate of the protective effect of chocolate. We have no information on how changes in chocolate consumption may have affected a participant's risk of AF. Chocolate intake and covariate data were only available at baseline and, for most participants, in the fifth year of follow-up and may have changed over the 13.5 years of follow-up, resulting in some non-differential misclassification of exposure which would reduce the power to detect an association. In addition, this study was limited to cases with a diagnosis of AF as a primary cause. We did not have information on cases of silent AF, elective DC cardioversions or AF reported in outpatient clinics and emergency room visits. Therefore, it is likely that we substantially underestimated the overall incidence of AF in the population. However, the restriction to diagnosed incident AF cases should not affect the validity of the current study since the identification of diagnosed

symptomatic AF is unlikely to be impacted by levels of habitual chocolate intake. Finally, this study and the prior studies identified in our systematic review were primarily composed of Caucasian participants, and the results may not be generalisable to other populations if the association is modified by genetic factors.

Despite these limitations, our study has many strengths including a large sample size, a prospective population-based design, detailed data on diet and factors potentially related to exposure and outcome, and almost complete follow-up of the study cohort over many years.

CONCLUSIONS

Participants with higher levels of chocolate intake had a lower rate of clinically apparent incident AF or flutter. Future research is necessary to confirm this finding and to determine whether high levels of chocolate intake are associated with higher AF risk.

Key messages

What is already known on this subject?

Several studies have reported cardiovascular benefits of chocolate intake, but only two studies with discrepant findings have examined the association between chocolate intake and risk of atrial fibrillation (AF).

What might this study add?

In this large prospective cohort study we found that, compared with individuals reporting chocolate intake less than once per month, the rate of AF was lower for people consuming chocolate regularly, with similar results for men and women.

How might this impact on clinical practice?

Chocolate intake may be inversely associated with AF risk. Therefore, dark chocolate may be a healthy snack option that helps to prevent the development of AF.

HEART

Regular chocolate consumption may be linked to lower risk of heart flutter (atrial fibrillation)

Associations strongest for 1 serving/week for women and 2-6 servings/week for men, findings show

Regular chocolate consumption may be linked to a lower risk of developing the heart rhythm irregularity atrial fibrillation, also known as heart flutter, finds research published online in the journal **Heart**.

The associations seemed to be strongest for 1 weekly serving for women and between 2 and 6 weekly servings for men, the findings suggest.

Atrial fibrillation affects more than 33 million people worldwide, with one in four adults likely to develop it at some point during the life course. It's not clear exactly what causes it, but there is currently no cure, and no obvious contenders for prevention either.

Given that regular chocolate consumption, particularly of dark chocolate, has been linked to improvements in various indicators of heart health, the researchers wanted to see if it might also be associated with a lower rate of atrial fibrillation.

They drew on 55,502 (26,400 men and 29,100 women) participants, aged between 50 and 64, from the population-based Danish Diet, Cancer and Health Study.

Participants provided information on their usual weekly chocolate consumption, with one serving classified as 1 ounce (30 g). But they were not asked to specify which type of chocolate they ate. Most chocolate eaten in Denmark, however, is milk chocolate (minimum 30 per cent cocoa solids).

Information on heart disease risk factors, diet, and lifestyle—roughly one in three smoked—was obtained when the participants were recruited to the study. Their health was then tracked using national registry data on episodes of hospital treatment and deaths.

Those at the higher end of chocolate consumption tended to consume more daily calories, with a higher proportion of these coming from chocolate, and to be more highly educated than those at the lower end of the scale.

During the monitoring period, which averaged 13.5 years, 3346 new cases of atrial fibrillation were diagnosed. After accounting for other factors related to heart disease, the newly diagnosed atrial fibrillation rate was 10 per cent lower for 1-3 servings of chocolate a month than it was for less than 1 serving a month.

This difference was also apparent at other levels of consumption: 17% lower for 1 weekly serving; 20 per cent lower for 2-6 weekly servings; and 14 per cent lower for 1 or more daily servings.

When the data were analysed by sex, the incidence of atrial fibrillation was lower among women than among men irrespective of intake, but the associations between higher chocolate intake and lower risk of heart flutter remained even after accounting for potentially influential factors.

The strongest association for women seemed to be 1 weekly serving of chocolate (21 per cent lower risk), while for men, it was 2 to 6 weekly servings (23 per cent lower risk).

This is an observational study, so no firm conclusions can be drawn about cause and effect, added to which milk may lower levels of the beneficial compounds in chocolate thought to have a role in the favourable associations found between chocolate and heart health.

And more often than not, chocolate is eaten in high calorie products containing fat and sugar, which are generally not considered good for heart health.

But say the researchers: “Despite the fact that most of the chocolate consumed in our sample probably contained relatively low concentrations of the potentially protective ingredients, we still observed a robust statistically significant association.”

However, a linked editorial sounds a note of caution. Doctors from the Duke Center for Atrial Fibrillation in North Carolina, USA, highlight that the chocolate eaters in the study were healthier and more highly educated—factors associated with better general health—which might have influenced the findings.

Secondly, the researchers were not able to take account of other risk factors for atrial fibrillation, such as kidney disease and breathing problems at night (sleep apnoea). And the study included only diagnosed cases of atrial fibrillation, making it difficult to determine if chocolate is associated with a lower risk of atrial fibrillation or only with obvious symptoms, the editorialists suggest.

Lastly, cocoa solid levels vary in different parts of the world, so the findings might not apply in countries with lower levels, they add.

Nevertheless, Drs Sea Pokorney and Jonathan Piccini say: “Regardless of the limitations of the Danish chocolate study, the findings are interesting and warrant further consideration, especially given the importance of identifying effective prevention strategies for [atrial fibrillation],” which have so far proved elusive.
