Introduction PET imaging, using the bone tracer Na^{18}F, allows the non-invasive location of atherosclerotic plaques that are at risk of rupture. However, the spatial resolution of PET is only 4–5 mm, limiting the mechanistic information this technique can provide.

Methods In this project, the use of fluorescence and Raman imaging to elucidate the mechanism of microcalcification within atherosclerotic plaques has been investigated.

Results and conclusion A fluorescent probe to specifically detect calcium has been synthesised: it has been shown to: selectively bind to hydroxyapatite (HAP), permit visualisation and quantification of HAP in both vascular and bone cell models, effectively stain cultured aortic sections and whole mouse aorta for OPT imaging.

It is believed that the biosynthetic pathway to HAP passes through a series of transitional states; each of these has different structural characteristics which can be studied using Raman spectroscopy. In particular, HAP has a strong characteristic Raman peak at 960 cm\(^{-1}\). An increase in HAP concentration has been detected by Raman in both calcified cell models and aortic sections.

Building on these preliminary data, fluorescence and Raman imaging of both healthy and atherosclerotic tissue are planned.

PP2A: A GUARDIAN AT THE GATES?

Endothelial junction proteins that regulate movement across the vascular system, are modulated through phosphorylation. However, the role of protein phosphatase 2A (PP2A) mediated dephosphorylation in modulating permeability of the blood-brain barrier remains unclear. This study investigates the role of PP2A inhibition on VE-cadherin and PECAM-1 abundance, and whether it affects brain microvascular permeability.

Human brain microvascular endothelial cells (hBMECs) were exposed to okadaic acid (OA, 10 nM), or dimethylsulphoxide (DMSO; 0.01% v/v) for 24 hour. Protein expression was determined using immunoblotting. PP2Ac activity was measured by an immunoprecipitation assay (Millipore). Proteasomal degradation was investigated using MG-132 (2 \(\mu\)M). hBMEC/D3 cells were transfected with CIP2A and SET plasmids (pcDNA3.1) using polyethylenimine.

PP2Ac methylation by LCMT-1, preventing the assembly of the holoenzyme. As such, PP2A-mediated regulation of the blood brain barrier, might be a target of therapeutic value.

The accumulation of vascular smooth muscle (SM)-like cells within the intima contributes significantly to intimal medial thickening (IMT) and vascular remodelling typical of arteriosclerotic disease. The source of these cells remains controversial. Light has emerged as a powerful tool to interrogate cells label-free and facilitates discriminant observations both in vitro and in vivo. The auto-fluorescence (AF) profile of individual cells isolated from arteriosclerotic vessels, captured on V-cup array and interrogated across five wavelengths using a novel Lab-on-a-Disc platform, was significantly increased at the 565±20 nm wavelength concomitant with a reduction in Myh11 expression, when compared to differentiated vascular smooth muscle cells (SMC) from control vessels. In vitro, TGF-β1 promoted myogenic differentiation of murine bone-marrow derived Sca1+/CD44+/mesenchymal stem cells (MSC) and murine Sca1+C3H 10 T1/2 cells concomitant with enrichment of the specific SMC epigenetic histone mark, H3K4me2 at the Myh11 promoter, Myh11 promoter transactivation and increased SMC differentiation marker mRNA and protein expression. Myogenic differentiation resulted in a significant increase in the AF intensity across 565±20 nm wavelength, an effect not observed for TGF-β1 treated RAMOS human B lymphocytes but mimicked by Notch activation of resident Sca1+ multipotent vascular stem cells (MVSCs) with Jagged1 and inhibited following elastic and collagen III depletion, respectively.
