Cardiac rehabilitation in older adults: is it just lifestyle?

Tone M Norekvål ^{1,2} Heather G Allore^{3,4}

INTRODUCTION

It is well established that there are patients who are less likely to access cardiac rehabilitation (CR). They include women, those of low socioeconomic status, patients living in rural areas, ethnocultural minorities and older adults. Reflecting on Jepma *et al*'s paper in *Heart*,¹ we turn our focus to CR programmes for older adults. Despite CR being a class I recommendation in the European Society of Cardiology guidelines,² there continues to be a significant underutilisation of CR in older adults. Knowledge gaps across current evidence-based practice guidelines pertain to lack of sufficient data to provide sound recommendations for older adults. This is in part due to the fact that studies on which guidelines are based enrolled a low number of older adults or included older adults with few comorbidities.³

Effect of CR in older adults

In their paper in *Heart*, Jepma *et al*¹ investigated the effect of nurse-coordinated referral to a comprehensive set of three lifestyle interventions (physical activity, weight reduction and/or smoking cessation) to usual care in older (≥ 65 years) versus younger (< 65 years) patients with coronary artery disease (the RESPONSE-2 trial). The trial included 824 patients from 15 centres in the Netherlands. The primary outcome was the proportion of patients with improvement at 12-month follow-up in one or more lifestyle risk factors. Despite more adverse cardiovascular risk profiles and comorbidities among older patients, nurse-coordinated referral to a community-based lifestyle intervention was at least as successful in improving lifestyle risk factors in older as in younger

patients. Adherence in older adults was excellent, with over 87% completing the physical activity programme. In fact, older adults attended significantly more weight reduction sessions and over 71% completed the smoking cessation programme.

The effect of CR in older adults is not new.⁴ However, it has not reached to the forefront of clinical care. Rather, the main focus has been to have (male) myocardial infarction survivors back to work. From a health economic standpoint, this may seem logical. However, it underestimates the costs related to healthcare. New cardiac events leading to readmission to hospital and need of assistance from primary care, as well as the unpaid labour of informal caregivers, are resource-demanding and influence quality of life. In some healthcare systems the costs of home-based programmes, which are of particular relevance for older adults given challenges with transport and the burden of informal caregivers, are not covered. Therefore, implementation and dissemination across a variety of healthcare systems remain challenging.

Referral, accessibility and modes of delivery

The RESPONSE-2 trial makes important points regarding referral to secondary prevention programmes and making the programmes easily accessible. Nurse referral to secondary prevention programmes performed in a systematic manner can be a first step to address the suboptimal uptake of CR. However, authority to refer to CR is dependent on country and healthcare system. Further, the mode of delivery and the setting are of importance. CR has over time evolved from a single-component exercise training programme into a comprehensive lifestyle programme targeting traditional risk factors delivered through group-based sessions. However, the setting (centre-based vs home-based, or a combined model) is especially relevant to older adults. Group-based CR may indirectly address social isolation, while the modes of delivery of some components such as the use of mobile health applications and internet-based training

for e-cardiac rehabilitation (eCR) are an innovative approach ready to be tested even among the oldest adults. For older adults with barriers to attending group-based setting, eCR may provide an avenue to social connection. eCR requires a certain level of e-health literacy and may not be applicable for those with cognitive impairment or visual impairments. Large observational studies are under way to map out the level of e-health literacy and use of devices and technologies in real-world coronary artery disease populations, including older adults.⁵ Using internet-based programmes combined with direct contact follow-up showed a high completion rate in RESPONSE-2.¹

Targeting frailty and multimorbidity

The RESPONSE-2 trial highlights that it is time to act. However, it should be noted that those ≥ 65 years in the trial were fairly healthy, with about 55% having no known history of cardiovascular disease and only about 28% with a history of dyslipidaemia. In fact, among those ≥ 65 years, only 66% were eligible for weight reduction, 21% eligible for a physical activity programme and a mere 13% eligible for the smoking cessation programme. Even with such low proportions eligible for each CR component, among those ≥ 65 years, there were meaningful effects of weight reduction and positive effect estimates for physical activity and smoking cessation, which were diluted by those ineligible. If Jepma *et al*¹ had performed an 'as treat' analysis of those eligible, it is likely they would have seen a larger effect and tighter CI for each of these CR components. In real-world populations of older adults, it is likely that moving beyond traditional risk factor management is a path forward. The older adult population is very heterogeneous with respect to their medical, physical function, brain health and social factors. Chronological age does not always correspond with health status. For those in poor health, issues brought on by multiple coexisting conditions and posthospital deconditioning deserve attention. Such programmes are rare in everyday CR practice.

There is a possible continuum of CR care from the traditional secondary prevention programme to the programme tested in the RESPONSE-2 trial, and further to an array of components addressing medical, physical functioning, brain health and social vulnerability factors. Tailoring traditional CR components as well as extending the array

Figure 1 Moving beyond traditional cardiac rehabilitation programmes in multimorbid older adults with functional decline by adding novel and tailored components targeting vulnerability factors.

of components for the complex older patient follow how clinical care is delivered. That is, the patient receives a comprehensive assessment, and only the conditions present, which may be modified through a therapy or other interventions, are treated with components (figure 1). For example, for patients with polypharmacy there could be a medication review, for patients with sarcopaenia there could be weight bearing and/or balance exercises and nutrition optimisation, and for patients with brain health deficits, such as depression, there could be a variety of therapeutic approaches dependent on the diagnosis and severity. Recognising post-treatment delirium and cognitive impairment in some patients will highlight the need to include informal caregivers into the CR programme.

Frail older adults are generally excluded from CR programmes and trials under the notion that older adults do not have sufficient exercise capacity. Sarcopaenia as part of posthospital deconditioning is common, and loss of muscle mass per day of bed rest is significant. Thus, CR components, such as physical activity, which may delay frailty and reduce sarcopaenia, should be encouraged and used as a measurable outcome. However, as called for by European CR leaders, we need to better understand whether exercise-based CR may change frailty status in cardiovascular patients.⁶ There is a need for large, sufficiently powered, exercise-based CR trials also targeting older adults in order to fill this knowledge gap.

WAY FORWARD

There is a paucity of data on the impact of diagnostic and therapeutic interventions on key outcomes that are

particularly important to older patients, such as quality of life, physical function and maintenance of independence.³ The SILVER-AMI study enrolling 3000 patients ≥ 75 years showed that functional mobility was the strongest predictor of 30-day readmission—a variable previously not included in readmission risk models.⁷ Adding to these measures to real-life coronary artery disease populations, the CONCARD^{PCI} study⁵ will expand these findings by allowing for comparisons across all age groups and including patient-centred outcomes pertinent to older adults. Both the SILVER-AMI and CONCARD^{PCI} studies lay foundations for novel CR interventions for older adults. The eligible population for CR is greying, as is the general population, and more complex patients will require novel and tailored approaches in CR and cardiac care (figure 1).

Take home message

The time to include cardiac rehabilitation (CR) as a first-line follow-up treatment for older adults in cardiac care is overdue. The RESPONSE-2 trial adds to the evidence base on older adults receiving benefits at the same level as younger patients by showing positive effect estimates and strong adherence among older adults randomised to weight reduction, physical activity and smoking cessation components of traditional CR. CR programmes may be expanded to include evidence-based practices to modify additional vulnerability factors of the complex older adults in a tailored manner. Given the mix of medical, physical, brain health and social vulnerability factors, a tailored CR programme is timely. For some patients, their informal caregivers may play an important role

in their adherence to CR programmes; therefore, we need to rethink CR for older adults. Such opportunity for clinical practice—and for research—to have impact on cardiac care should not go unrecognised.
