During the 2-year period July 1970 to July 1972, balloon atrial septostomy was performed in 12 patients with total anomalous pulmonary venous return, ranging in age from 4 days to 1 year, and in weight from 2.27 to 6.80 kg. After septostomy, 9 of the 12 patients were improved both clinically and haemodynamically. Of these 9 patients, 1 died inexplicably 1 week after the septostomy. In the remaining 8 patients, improvement was maintained during follow-up ranging from 7 months to 2 years. Repeat cardiac catheterization in 4 patients documented continued haemodynamic improvement.

Of the 12 patients, 3 were not helped by the septostomy and required operation within a few days. In 2 of these infants, the opening created by the septostomy was found at operation to be too small to have been considered beneficial, yet both of these patients had had less than a 1 mmHg mean atrial pressure gradient before septostomy. The third patient, who had infradiaphragmatic return, had a large interatrial communication confirmed at operation.

Based on the results achieved in these patients, balloon atrial septostomy is now recommended at the time of the initial cardiac catheterization in all infants with total anomalous pulmonary venous return. The procedure is less likely to be successful in infants over 3 months of age, and in those with infradiaphragmatic pulmonary venous return. The haemodynamic improvement obtained by successful septostomy in the young infant should allow delay of operation until a more optimal age.

The potential value of balloon atrial septostomy for infants with total anomalous pulmonary venous return, described by Miller *et al.* (1967) and by Serrato *et al.* (1968), has been questioned because of the frequent lack of significant interatrial pressure gradient (Leachman *et al.*, 1969; Gathman and Nadas, 1970). The presence of only a small foramen ovale discovered at necropsy in an infant who shortly before her death was denied balloon atrial septostomy on the basis of equal atrial pressures led the authors to the use of the balloon catheter for all infants with total anomalous pulmonary venous return, both to assess the size of the atrial communication and to perform balloon atrial septostomy when feasible. This report discusses the results of the use of the balloon catheter in patients with total anomalous pulmonary venous return over a 2-year period.

Received 29 December 1972.

Subjects and methods

Over the 2-year period July 1970 to July 1972, balloon atrial septostomy was performed in 12 of the 20 patients with total anomalous pulmonary venous return who underwent cardiac catheterization at Texas Children's Hospital (Table). Balloon atrial septostomy was felt to be inadvisable in the other 8 of the 20 patients with total anomalous pulmonary venous return. Of the 8, 5 were over 1 year of age, 1 had infradiaphragmatic return, and 2 had large atrial communications as determined by unobstructed withdrawal of a fully inflated balloon across the atrial septum. Of the 12 patients, 2 (Cases 1 and 2) who had balloon atrial septostomies were described in a previous report (El-Said, Mullins, and McNamara, 1972).

The diagnosis of total anomalous pulmonary venous return was confirmed by selective angiography in each patient. During each catheterization, effort was made to enter the left atrium, left ventricle, common anomalous pulmonary venous channel, right atrium, right ventricle, pulmonary artery, and pulmonary artery wedge position. Entry into each of these sites enabled documentation of any pressure gradient between the left and right atrium, between the anomalous pulmonary venous channel and

TABLE Summary of data from patients who underwent balloon atrial septostomy

Case No.*	Age and sex	Weight (kg)	Type of return	Pulmonary venous obstruction	Follow-up period (to July 1972)
1	3 mth M	4.0	Coronary sinus	Absent	Operation after 7 mth
2	1 mth M	3.0	Coronary sinus	Mild	2 yr
3	1 mth F	3.8	Coronary sinus	Absent	1 yr
4	35 dy M	5.0	Vertical vein	Absent	Died suddenly after 1 wk
5	1 mth M	5.4	Coronary sinus	Absent	14 mth
6	10 mth M	6.6	Vertical vein	Mild	14 mth
7	7 mth F	5.4	Vertical vein	Mild	5 mth
8	12 mth M	5.9	Right lung: right superior vena cava Left lung: vertical vein	Moderate	22 mth
9	12 mth M	6.7	Left upper lobe: vertical vein Others: coronary sinus	Mild	Operation after 11 mth
10	4 dy F	3.0	Right superior vena cava	Absent	Operation after 2 mth
11	8 dy M	2.3	Infradiaphragmatic	Severe	Operation shortly after
12	4 mth F	4.7	Coronary sinus	Absent	Operation shortly after

* Note: Cases 1 to 9 improved after septostomy; Cases 10 to 12 did not improve.

the right atrium, or between the pulmonary artery wedge position and the right atrium. Both phasic and mean pressures were recorded from each location. In order to visualize any areas of pulmonary venous obstruction, large film selective angiocardiology or 35 mm cine-angiography was used, with separate injections, when permissible, into the right and left pulmonary arteries. In some patients, injections were made directly into the common anomalous pulmonary venous channel. The criteria for pulmonary venous obstruction included one or more of the following: (1) pulmonary artery wedge mean pressure 10 mmHg higher than right atrial mean pressure, (2) mean pressure in the common pulmonary venous trunk at least 10 mm higher than right atrial mean pressure, (3) angiocardiology evidence of discrete localized obstruction with delayed emptying in the pulmonary venous channels, and (4) infradiaphragmatic return to ductus venosus or to portal vein.

The balloon atrial septostomy was performed using the technique of Rashkind and Miller (1966) originally described for patients with transposition of the great arteries. In patients with total anomalous pulmonary venous return, the usual methods of identifying the left atrial position of the balloon catheter by either (1) entering pulmonary veins, (2) recording a significantly higher left than right atrial pressure, or (3) recording a higher left atrial oxygen saturation are all invalid. In total anomalous pulmonary venous return, the catheter location in the left atrium can only be positively identified by the injection through a double lumen catheter of a small amount of contrast under fluoroscopic visualization. Balloon withdrawal across the septum was performed promptly after balloon inflation to avoid prolonged obstruction of the foramen ovale and, thus, total venous return to the left side of the heart.

After balloon atrial septostomy, systemic and pulmonary arterial oxygen saturations and pressures were remeasured. If both haemodynamic and clinical

improvement were evident, the patients were discharged to be followed for variable periods of time until they reached a suitable age and weight for elective total surgical correction. If significant clinical improvement was not initially evident or maintained, surgical correction was attempted shortly after the cardiac catheterization.

Results

Atrial septostomy was performed without complication in the 12 patients (Fig. 1 and 2). After balloon atrial septostomy, 9 of the 12 patients (Cases 1 to 9) were improved clinically, as evidenced by an improvement or alleviation of pulmonary oedema and a decrease in cardiac enlargement (Fig. 3). In the 9 patients who improved clinically, the systolic pulmonary artery and mean right atrial pressures, as well as mean right to mean left atrial pressure gradient, had each decreased significantly (Fig. 4). There was no change in systolic systemic or mean left atrial pressures. Of these 9 patients, 1 died in-

FIG. 4 The mean and standard error of the systolic systemic blood pressure (SSBP), systolic pulmonary blood pressure (SPBP), mean right atrial (MRA), mean left atrial (MLA), and MRA-MLA before and immediately after balloon atrial septostomy (BAS) in the 9 patients who showed definite clinical improvement.

FIG. 5 The mean and standard error of the systemic oxygen saturation, systemic systolic blood pressure, pulmonary systolic blood pressure, right atrial mean (MRA), mean left atrial (MLA), and mean right atrial to mean left atrial pressure gradient (MRA-MLA) before and immediately after balloon atrial septostomy, as well as 3 to 17 months later in 4 patients.

explicitly 1 week after septostomy. In the other 8 patients, improvement was maintained during observation periods ranging from 7 months to 2 years. Repeat cardiac catheterization in 4 patients indicated further haemodynamic improvement (Fig. 5).

Of the 12 patients, 3 (Cases 10 to 12) were unimproved by the septostomy and required operation within a few days. In 2 of these infants, the opening created by the septostomy was found at the time of operation to be too small to have been beneficial, though both patients had less than a 1 mmHg mean atrial gradient both before and after septostomy. The third patient had a large interatrial communication confirmed at operation but had infradiaphragmatic return.

Discussion

The condition of total anomalous pulmonary venous return, is actually a group of anomalies with different

anatomical and haemodynamic types, most of which can be corrected surgically with structural and functional cure. The timing of the operation remains the important question considering the high natural mortality in the untreated infant and the high surgical risk in this age group (Mustard, Keith, and Trusler, 1962; Cooley, Hallman, and Leachman, 1966; Leachman *et al.*, 1969; El-Said *et al.*, 1972). Using profound hypothermia and total circulatory arrest, Barratt-Boyes, Simpson, and Neutze (1971) and Dillard, Mohri, and Merendino (1971) reported the successful surgical correction of several infants with total anomalous pulmonary venous return. Gersony *et al.* (1971) also reported the successful correction of infants with total anomalous pulmonary venous return under the age of 5 months using normothermic cardiopulmonary bypass. These reports are encouraging; however, until the time that such results of early surgical treatment are obtainable in all centres, balloon atrial septostomy can offer a safe and effective form of palliative treatment in most of these patients with a greater overall survival.

The foramen ovale has been reported to be a site of obstruction in patients with total anomalous pulmonary venous return (Burchell, 1956; Burroughs and Edwards, 1960; Serrato *et al.*, 1968; Miller *et al.*, 1967). Bonham-Carter, Capriles, and Noe (1969) reported that all their patients surviving beyond the first year of life had a secundum atrial septal defect. Miller *et al.* (1967) and Serrato *et al.* (1968) performed balloon atrial septostomy in 10 infants who were in congestive heart failure and who had no extracardiac pulmonary venous obstruction, obtaining clinical and haemodynamic improvement in most of the patients. In a previous study (El-Said *et al.*, 1972), it has been documented that patients with total anomalous pulmonary venous return and small foramen ovale may have no pressure gradient across the atrial septum. The absence of pressure gradient in the presence of a small atrial communication is explained by the greater compliance of the right atrium than the left atrium (Cournand *et al.*, 1947) which allows a large volume to develop within the right atrium without concomitant high pressure.

In total anomalous pulmonary venous return, pulmonary as well as systemic venous blood returns to the right atrium. The preferential flow is to the right ventricle. Even minor obstruction between the right and left atrium will potentiate this type of preferential flow. In patients with total anomalous pulmonary venous return and inadequate atrial communication, the majority of the circulating blood is sequestered in the lungs, right heart, and large systemic veins. This preferential flow to the right heart often results in suprasystemic pulmonary

artery pressure. Balloon septostomy results in an increased blood flow to the left atrium and systemic circulation together with a decrease in pulmonary blood flow producing remarkable clinical and haemodynamic improvement.

Balloon atrial septostomy in infants with total anomalous pulmonary venous return is technically more difficult than in other anomalies because of the relatively small left atrium and the difficulty in determining the actual catheter location in the absence of the usual landmarks of the pulmonary veins. Using a double lumen catheter and injecting a small amount of contrast medium is essential to identify unequivocally the catheter position before the balloon withdrawal. Balloon withdrawal across the atrial septum must be rapid, since the inflated balloon obstructs the entire systemic flow. Serrato *et al.* (1968) reported a patient with total anomalous pulmonary venous return who died due to rupture of the balloon. However, no complications related directly to the septostomy were encountered in our patients.

Conclusions

A small atrial communication does not necessarily produce an interatrial pressure gradient in patients with total anomalous pulmonary venous return. A balloon catheter should be used routinely in infants with total anomalous pulmonary venous return to measure the size of the atrial communication and to perform septostomy when resistance to balloon withdrawal is encountered. Though balloon atrial septostomy has been performed for relatively older patients, the procedure is most likely to be successful in infants under 3 months of age, in those with large pulmonary flow, and in patients without significant pulmonary venous obstruction. The haemodynamic improvement obtained by successful septostomy in any infant with total anomalous pulmonary venous return may allow delay of operation until a more optimal age.
