His bundle recordings in paroxysmal atrioventricular block produced by carotid sinus massage

Agustin Castellanos, Ruey J. Sung, Damiao Cunha, and Robert J. Myerburg

From the Division of Cardiology, Department of Medicine, University of Miami School of Medicine and the Medical Service, Veterans Administration Hospital, Miami, Florida, U.S.A.

Electrograms from the bundle of His were recorded in two patients with acute myocardial infarction during paroxysmal atrioventricular block induced by carotid sinus massage. From the viewpoint of the surface electrocardiogram this arrhythmia was considered as a form of Type II (Mobitz) block, the onset of which was related to a decrease in atrial rate.

In the first patient, the conduction disturbance appeared at the AH, and in the second patient at the HV, level. Paroxysmal atrioventricular block could be explained by assuming the existence of: (a) vagal effects at the atrioventricular node or upper His bundle (Case 1) and at 'lower' His bundle (Case 2); or (b) phase 4 block related to diastolic depolarization in 'upper' (Case 1) and 'lower' (Case 2) parts of the His bundle; or (c) vagal effects at the atrioventricular node (Case 1) and phase 4 block due to diastolic depolarization within the bundle of His (Case 2).

Several recent publications have discussed the electrocardiographic characteristics of a conduction disturbance which in 1933 was classified as paroxysmal atrioventricular block (Rosenbaum *et al.*, 1973; Jensen *et al.*, 1973; Testoni, Montemurro, and Tommaselli, 1973; Sachs and Traynor, 1933; Slama *et al.*, 1969; Coumel *et al.*, 1971). The latter was considered to have been present when normal or practically normal atrioventricular conduction was suddenly and unexpectedly followed by total interruption of AV conduction (Rosenbaum *et al.*, 1973). Without further qualification, this description applies to Type II Mobitz AV block (Mobitz, 1924).

However, Rosenbaum and co-workers consider that there are several 'varieties' of paroxysmal atrioventricular block. These authors as well as Testoni *et al.* (1973) and Coumel *et al.* (1971) placed special emphasis on a form of block which was initiated by a slowing of the atrial rate. The purpose of this report is to present His bundle electrograms in two patients with a similar type of paroxysmal atrioventricular block and to discuss its possible genesis.

Case reports

Case 1

Fig. 1 was obtained from a 45-year-old woman, with a 20-year history of recurrent tachyarrhythmias, who was

Received 10 December 1973.

admitted because of an acute antero-septal myocardial infarction. A pacemaker was introduced on the fifth day after infarction when she developed drug-resistant sinus bradycardia. The latter alternated with paroxysms of supraventricular tachycardia. During sinus rhythm, the PR intervals and QRS complexes measured 140 msec and 80 msec, respectively (Fig. 1).

His bundle electrograms were recorded on the tenth post-infarction day, with the purpose of evaluating the arrhythmia and optimal drug therapy (Fig. 2). The conducting intervals measured from the first two (sinus) beats had the following values, in msec (figures in parentheses indicate normal ranges in our laboratory (Castillo and Castellanos, 1971)): PA:40 (20-40); AH:50 (50-120); and HV:50 (35-55).

Fig. 2 and 3 are continuous tracings showing the onset and termination of carotid sinus massage (arrows pointing downward). In Fig. 2 the first non-conducted (fifth) P wave was preceded by AV intervals of constant value. On the other hand, the PP intervals showed a gradual prolongation: 520 msec, 540 msec, and 700 msec. Hence, the fifth P wave was blocked when the PP interval was prolonged to 700 msec. Thereafter a transient period of 'complete' atrioventricular block occurred from the end of Fig. 2 to the last beat in Fig. 3. During this period the PP intervals were still longer than control. His bundle recordings showed that the atrial (A) impulses (and of course the P waves) were not followed by H deflections. Hence, the block occurred between the atria and the site, within the His bundle, from which the H deflection was recorded.

During the period of atrioventricular block the

FIG. 2 (Case 1) His bundle recordings showing paroxysmal atrioventricular block appearing during sinoatrial slowing. The first blocked P wave was preceded by PR intervals of constant (normal) duration. Onset of carotid sinus massage is indicated by vertical arrow pointing downward. The conduction disturbance occurred between the low right atrial (A) deflection and the site from which the His (H) bundle electrogram was recorded. The last two ventricular complexes were slightly wider than the first four. The retrograde H deflection appeared 5 msec after onset of QRS. In this Fig, as well as in Fig. 3 and 5 paper speed was 100 msec. HBE=bipolar electrogram recorded from the His bundle area. All values are expressed in msec.

FIG. 3 (Case 1) Termination of carotid sinus massage (vertical arrow) followed by a return to sinus rhythm (last beat).

ventricular rhythm originated below the so-called bifurcation of the His bundle (in the bundle-branches or in the divisions of the left branch). This assumption was supported by the slightly more deformed and somewhat wider (90 msec) QRS complexes and by (retrograde) activation of the His bundle 5 msec after that of the ventricles (VH interval of 5 msec). A His bundle rhythm was excluded, since the QRS morphology and HV intervals would have been similar to those of control beats (Castellanos *et al.*, 1972).

In Fig. 3, the third (wide) QRS complex was a ventricular extrasystole. Retrograde activation of the affected areas probably terminated the episode of paroxysmal atrioventricular block, since the fourth ventricular complex, preceded by a P wave of abnormal configuration, was conducted from the atria with a short PR interval (ectopic atrial rhythm?). Finally, the last beat had the same atrioventricular conduction intervals and QRS configuration as the first two beats in Fig. 2 (which served as control).

To summarize, in this patient with narrow QRS complexes, paroxysmal atrioventricular block occurred when the rate was slowed by carotid sinus massage. The con-

duction defect occurred between the atria and the site from which the His bundle deflection was recorded. Spontaneous atrioventricular block was not seen in this case.

Case 2

The tracings depicted in Fig. 4 and 5 were obtained from a patient with recent myocardial infarction. The top strip in Fig. 4 (day 1) shows acute inferior wall 'injury', possible incomplete left bundle-branch block, and abnormal left axis deviation probably caused by left anterior hemiblock. In the bottom strip (day 3), the inferior infarction had evolved and the initial r waves in leads II, III, and aVF had become smaller. The QRS complexes measured 110 msec. His bundle electrograms were recorded on the fourth post-infarction day (Fig. 5) when a catheter electrode was used because of sinus bradycardia (associated with first-degree atrioventricular block) not responding to drugs. The control atrioventricular conduction intervals (first QRS complex) had the following values: PA: 40 msec; AH: 95

FIG. 4 (Case 2) Twelve-lead electrocardiograms showing first-degree AV block, left anterior hemiblock, possible 'incomplete' left bundle-branch block, and ST-T changes suggestive of evolving inferior wall myocardial infarction.

FIG. 5 (Case 2) His bundle recordings showing paroxysmal atrioventricular block appearing during sinoatrial slowing. The first blocked P wave was preceded by PR intervals of constant (prolonged) duration. Onset of carotid sinus massage is at the start of the figure. In this case the conduction delay and block occurred between the site from which the His bundle electrogram was recorded and the ventricles.

msec; and HV: 105 msec. Since the QRS complexes only measured 110 msec, the prolongation of the HV interval (upper limit of normal: 55 msec) was attributed to a conduction delay within the His bundle itself, below the site from which the H deflection was recorded.

During carotid sinus massage, started at the beginning of the Fig., the atrioventricular conduction intervals remained unchanged until the fourth P wave failed to reach the ventricle after activating the His bundle. This P wave was blocked when the PP interval was increased (from a control value of 870 msec) to 905 msec.

Thereafter the fifth P wave was also blocked. It is not known if the last P wave really activated the ventricles (with a longer-than-control HV interval), since the electrocardiographic recorder was stopped after inscription of the corresponding T wave and started a few seconds later when the atrioventricular conduction intervals had attained their control values. An alternative, though less likely, explanation is that the last QRS complex originated in the 'low' His bundle, the H deflection not being recorded for technical reasons. Spontaneous second-degree or advanced atrioventricular block did not occur.

To summarize, in this patient without abnormally wide QRS complexes (but with prolonged HV intervals), paroxysmal atrioventricular block appeared when the atrial rate was slowed by carotid sinus massage. The conduction defect occurred between the site from which the His bundle deflection was recorded and the ordinary ventricular myocardium. Spontaneous atrioventricular block was not seen in this case.

Discussion

Electrocardiographic criteria for paroxysmal atrioventricular block and its relation with type II (Mobitz) second-degree atrioventricular block

In 1973, Rosenbaum and co-workers reviewed 18 cases (8 of their own and 10 from other authors) of paroxysmal atrioventricular block initiated by sinoatrial slowing in which atrioventricular conduction was resumed after an escape beat. Wide QRS complexes were seen in all cases except one. In most, if not all, of the tracings, the PR interval preceding the first non-conducted P wave had a constant duration. Type II (Mobitz) atrioventricular block is also usually characterized by its association with wide QRS complexes and by the fact that the first blocked P wave is not preceded by PR intervals of varying duration. However, classical type II (Mobitz) block need not be triggered by a decrease in atrial rate (Mobitz, 1924).

From the viewpoint of the surface electrocardiogram, the form of paroxysmal atrioventricular block occurring in the two patients described in the present report can be considered as a variant of

type II (Mobitz) atrioventricular block since the PR intervals preceding the first blocked P wave had a constant duration. This form of type II (Mobitz) block was initiated by sinoatrial slowing. In Case 1 it was terminated by a ventricular extrasystole. It should be stated that we have used the term type II (Mobitz) atrioventricular block in a descriptive (surface electrocardiographic) sense, being well aware that it can result from different mechanisms.

Site where conduction disturbance occurs in paroxysmal atrioventricular block

Although His bundle electrograms were not recorded, Rosenbaum *et al.* (1973) postulated that in 17 of the 18 cases they studied the conduction disturbance occurred below the bifurcation of the His bundle. In the remaining case, the His bundle itself was probably involved. Testoni *et al.* (1973) analysed the tracings of 11 patients. The affected region was believed to have been what they called the 'specific system' (presumably the infra-atrioventricular nodal specialized conducting system). In a case reported by Coumel *et al.* (1971) His bundle recordings showed that the block occurred within the His bundle or left bundle-branch.

Our two patients with acute myocardial infarction had paroxysmal atrioventricular block only during carotid sinus massage. In Case 2 (with a left anterior hemiblock and an inferior wall myocardial infarction) the block most probably involved an area of the His bundle located below the site from which the H deflection was recorded, therefore being similar to Case 17 of Puech *et al.* (1971), (reproduced as Fig. 77 of the textbook by Puech and Grolleau (1972)).

Case 1 resembled Case 4 of Rosen *et al.* (1971) in that the atrioventricular block (induced by carotid sinus massage) occurred at the 'AH level'. It should be stressed that, as mentioned by Puech and Grolleau (1972), Langendorf, Cohen, and Gozo (1972), and Narula (1973), block at the AH level need not always be located at the atrioventricular node, since the conduction defect can occur at the 'upper' His bundle, above the site from which the H deflection is recorded. Moreover, a 'split' H deflection might be present and the position of the catheter (in reference to the His bundle) can be such that only the distal deflection is recorded (Narula, 1973).

That the atrioventricular block in which the non-conducted P wave is preceded by constant PR intervals almost invariably occurs below the node further supports an infra-atrioventricular nodal origin for Case 1. Nevertheless, this assumption could not be proven, and based on the actual data

obtained the block could have occurred at either atrioventricular node or 'upper' His bundle.

Mechanism of paroxysmal atrioventricular block

According to Langendorf (1973), the mechanism postulated for the specific variety of paroxysmal atrioventricular block discussed by Rosenbaum *et al.* (1973) cannot be responsible for all, or even the majority of cases of type II Mobitz atrioventricular block.

Rosenbaum *et al.* (1973) believed that paroxysmal atrioventricular block precipitated by atrial slowing was related to 'hypopolarization plus spontaneous diastolic depolarization' (phase 4 block), when terminated by an escape beat, and to repetitive concealed conduction when atrioventricular conduction was re-established without an intervening ectopic beat. Coumel *et al.* (1971) described a case (proven by His bundle recordings) of paroxysmal, bradycardia-dependent, phase 4 block exposed by premature atrial beats. These authors did not attribute this conduction disturbance to a vagal-induced depression of conductivity. The vagal effects were thought to be indirect, that is, only related to the atrial slowing *per se*, which gave enough time (when the PP interval was decreased to a 'critical' level) for the atrial impulse to appear late in the cycle, on the phase 4 block range.

Explanations can be postulated in the two cases presented in this communication. For instance, the block could have been due to a vagal-related depression of conduction, which in Case 1 occurred at the atrioventricular node, or 'upper' His bundle, and in Case 2 at the 'low' His bundle. Against this assumption are long held views implying that the vagus does not significantly affect conduction within the ventricular specialized tissues. Nevertheless, Puech and Grolleau (1972) have observed that carotid sinus massage prolongs the AH interval (Fig. 67 and 76) in some cases and the HV interval in others (Fig. 77).

On the other hand, it is also possible that, in our two cases the atrioventricular block (induced by sinoatrial slowing) was a 'phase 4 block' related to diastolic depolarization occurring in the 'upper' His bundle (Case 1) and at the low His bundle (Case 2). Finally, two separate mechanisms might have been operating, namely, vagal-related atrioventricular nodal block in Case 1 and 'intra' His bundle phase 4 block in Case 2.

We hope that this preliminary report can stimulate further studies which can lead to a better understanding of the genesis of Type II Mobitz atrioventricular block.
