Mitral regurgitation in coronary heart disease

From the National Heart Hospital and Institute of Cardiology, London

Mitral regurgitation is a relatively common finding in coronary heart disease. In this series of 127 patients, selected with a view to coronary or left ventricular surgery on the basis of severity of symptoms, the incidence was 39 (31%). Mitral regurgitation is significantly more common in patients with a history or electrocardiographic evidence of previous myocardial infarction. Clinically it may present as a pan- or late systolic or even a mid-systolic, ejection type murmur at the apex or at the left sternal edge; but in 39 per cent of the patients with angiographic mitral regurgitation no murmur was present. Angiographically important mitral regurgitation (grades 2-4/4) was usually associated with a systolic murmur; this finding was independent of ejection fractions. Left ventricular enlargement clinically or radiographically is likely to accompany mitral regurgitation but left atrial enlargement (electrocardiographically or on chest x-ray) is a more reliable pointer to mitral regurgitation and pulmonary venous hypertension is even more strongly suggestive of its presence. The electrocardiographic signs of papillary muscle infarction were rare in this series (15%) and were not related to angiographic mitral regurgitation. There was no difference in the incidence of mitral regurgitation in association with anterior or inferior myocardial infarction or in distribution of coronary artery disease. There is, however, a higher incidence of mitral regurgitation in more severe coronary arterial disease ($P < 0.05$). The incidence of mitral regurgitation is significantly higher with reduction in left ventricular ejection fraction ($P < 0.001$), with rise in the left ventricular end-diastolic pressure ($P < 0.02$), and with abnormal contraction patterns, but the severity of mitral regurgitation is not significantly related to these findings.

The integrity of the mitral valve is dependent upon the complex functional and spatial interrelationships of the valvar ring, its leaflets with their pinioning chordae tendineae, and the papillary muscles which are anchored in the ventricular wall (Puff *et al.*, 1965; Silverman and Hurst, 1968; Burch *et al.*, 1971; Heikkilä, 1971). This complex mechanism may be impaired by reversible myocardial ischaemia, or necrosis and fibrosis. Thus mitral regurgitation is not an uncommon transient or permanent finding in coronary heart disease (Phillips *et al.*, 1963; Heikkilä, 1967, 1971; Burch *et al.*, 1971; De Pasquale and Burch, 1971).

It is the purpose of this paper to assess the significance of clinical, electrocardiographic, haemodynamic, and radiological findings, from plain chest radiographs and ventricular and coronary

angiocardiograms, with regard to the occurrence of mitral regurgitation in patients with proven coronary arterial disease. A preliminary report of this study was given to the British Cardiac Society (Gahl *et al.*, 1972).

Subjects and methods

Investigations were made on 127 patients (111 men with mean age of 51 ± 9.1 years and 16 women with mean age of 50.1 ± 15.8 years) with coronary heart disease being assessed with a view to aortocoronary venous bypass grafting or left ventricular surgery (Ross *et al.*, 1972). All were severely symptomatic with angina pectoris resistant to medical treatment or incapacitating congestive cardiac failure. Patients were examined clinically, by electrocardiography, plain chest radiography, phono- and apex cardiography, and cardiac catheterisation with left ventricular and coronary angiocardiography. Beta-blocking drugs were discontinued at least 24 hours before the investigation; other drugs were continued. Non-invasive investigations were performed at a time closely related to cardiac catheterisation in

70 unselected patients. Tracings were taken on a Cambridge Recorder at a paper speed of 100 mm/s with two microphones, one at the apex and the other at the left sternal edge. The pulse pick-ups were placed at the site of maximum apical impulse and on the external carotid artery.

Routine right and left cardiac catheterisations were performed followed by selective coronary angiography (Petch *et al.*, 1973). Mitral regurgitation was assessed from cineventriculograms in the right anterior oblique projection, and graded independently by two observers as slight, moderate, severe, and gross (grades 1 to 4). It was considered to be significant only if it occurred during normal systoles. In slight (grade 1) reflux there was only a faint puff of dye entering the left atrium; in moderate mitral regurgitation there was a distinct jet; in severe reflux there was a broad jet of dye passing across the mitral valve, and in grade 4 the entire left atrium was opacified immediately during the first systole with no distinct jet visible.

Left ventricular contraction on ventriculograms was graded as normal (1), local dyskinesia (2), aneurysm (3), or generalised dyskinesia (4). Local dyskinesia was defined as reduced but not absent inward systolic movement of part of the left ventricular wall compared with the adjacent wall. Aneurysm was defined as a localised enlargement of the ventricular cavity apparent in systole and usually in diastole, showing total lack of inward systolic movement, with or without paradoxical outward systolic movement. General dyskinesia was defined as poor overall contraction. The ejection fraction was measured using end-diastolic and end-systolic frames of one or more cardiac cycles. Cycles associated with arrhythmias were excluded. The films were not calibrated for magnitude which

precluded measurement of absolute volumes. The localisation and the extent of coronary arterial disease were judged from cineangiograms and additionally in some cases from cut films. The coronary circulation was considered as a three-vessel system with right, left anterior descending, and left circumflex vessels. A simple score system was used where normal arteries and less than 70 per cent stenosis was scored 1, 70 to 99 per cent stenosis scored 2, and total occlusion scored 3. χ^2 analysis was used for statistical comparisons.

Results

In the 127 patients, 39 had angiographically demonstrable mitral regurgitation, which were subdivided into 13 patients with grade 1, 13 with grade 2, 11 with grade 3, and 2 with grade 4 regurgitation. Particular attention was paid to clinical signs suggestive of mitral regurgitation (systolic murmurs, a third heart sound, and palpable rapid filling waves).

Of the 39 patients with angiographically demonstrable mitral regurgitation, 24 (62%) had a systolic murmur which was apical in 22 and parasternal in 2. The apical murmur was pansystolic in 16, mid-systolic in 3, and late-systolic in another 3 patients. The remaining 15 of the 39 patients with mitral regurgitation, however, had no systolic murmur. Angiographically important mitral regurgitation (grades 2 to 4/4) was usually associated with a systolic murmur and this finding was independent of left ventricular ejection fraction (Table 1).

In 29 patients, a murmur was heard without angiographic evidence of mitral regurgitation. In 13 patients this was apical, in 14 at the lower sternal

edge, and in 2 cases at the pulmonary area.

The clinical and electrocardiographic findings were related to the presence or absence of angiographically demonstrable mitral regurgitation (Table 2). The duration of the history of angina pectoris did not differ in those with and without mitral regurgitation. History of previous myocardial infarction was significantly more common in patients with mitral regurgitation ($P < 0.05$). Symptoms of heart failure were more frequent among patients with than without mitral regurgitation (24/39=62% and 42/88=48%, respectively) as was palpable left ventricular enlargement (23/39=59% and 28/88=32%, respectively) but these differences were not statistically significant. A third heart sound was audible in 17 of the 88 patients (19%) without mitral regurgitation, and in 14 of the 39 patients (36%) with mitral regurgitation, and a fourth heart sound was present in 31 patients (35%) without mitral regurgitation and in 14 (36%) with mitral regurgitation. Evidence of previous myocardial infarction, however, was the only feature among these which showed a statistically significant difference between the two groups.

Of the 39 patients with mitral regurgitation 32 (82%) and of the 88 patients without mitral regurgitation, 55 (62%) had electrocardiographic signs of infarction ($P < 0.001$). Infarction was anterior in 48 patients, 17 of whom (35%) had mitral regurgitation, and inferior in 29 patients, 8 of whom (28%) had mitral regurgitation. Of the 10 patients with anterior and inferior infarction, 7 had mitral regurgitation. Criteria of papillary muscle infarction (Phillips *et al.*, 1963; Burch *et al.*, 1971) were positive in 10 patients without mitral regurgitation (11%) and in 9 patients with mitral regurgitation (23%). Electrocardiographic evidence

of left ventricular hypertrophy and left atrial enlargement (Morris *et al.*, 1964) was slightly more frequent in the group with than in those without mitral regurgitation. Finally electrocardiographic signs of left ventricular aneurysm were found in 31 per cent of patients with mitral regurgitation and in 22 per cent of patients without mitral regurgitation. None of these differences except that of the electrocardiogram of the myocardial infarction was statistically significant.

The rapid filling wave and the 'a' wave of the diastolic phase of the apex cardiogram did not parallel the radiological grade of mitral reflux (Table 1). They were most obvious in grade 2 mitral regurgitation.

The 'a' wave and the post 'a' left ventricular end-diastolic pressures ($P < 0.02$) and related pressures in the pulmonary circulation (Table 1) clearly show a more severe disorder of left ventricular haemodynamics in patients with mitral regurgitation than in those without. There is, however, no significant difference between patients in each mitral reflux group and impairment of left ventricular ejection fraction. Grade 2 mitral regurgitation, however, is associated with most severely reduced ejection fraction. There was no correlation between the left ventricular systolic pressure and the incidence of mitral regurgitation.

Table 3 summarises the findings on plain chest radiographs and angiocardiology in patients with and without mitral regurgitation. As with the electrocardiogram, evidence of atrial enlargement and left ventricular hypertrophy was slightly more frequently encountered in patients with than in those without mitral regurgitation, though 29 patients with mitral reflux did not show left atrial enlargement. Pulmonary venous hypertension, however, was a stronger pointer to mitral regurgitation and correlated fairly well with the haemodynamic data. Left ventricular cineangiograms showed a higher incidence of abnormal contraction in patients with mitral regurgitation than in those

Table 3 Plain chest radiographic and angiographic findings according to angiocardiology presence or absence of mitral regurgitation

	Patients without MR	Patients with MR
Enlargement of LV	17 (19%)	22 (56%)
Enlargement of LA	3 (3%)	10 (26%)
Pulmonary venous hypertension	13 (15%)	22 (56%)
Normal LV contraction	35 (40%)	7 (18%)
Localised dyskinesis	35 (40%)	12 (31%)

Generalised poor contraction	7 (8%)	10 (26%)

None of the differences between the two groups reached statistical significance ($P < 0.05$) using χ^2 analysis.

without (see Table 1). Selective coronary angiography revealed a relative preponderance of right coronary arterial and left anterior descending coronary arterial disease compared with circumflex disease. The incidence of mitral regurgitation was evenly distributed in the various patterns of coronary disease. However, there was a tendency to more severe degrees of coronary arterial disease (using the simple score system described) in patients with mitral regurgitation than in those without ($P < 0.05$).

Discussion

Mitral regurgitation is a relatively common finding in acute and chronic myocardial ischaemia (Friedberg, 1966; Heikkilä, 1971; Hurst and Logue, 1970; Segal and Likoff, 1964; Shelburne and Gorlin, 1972). It has been thought to be the result of (a) dysfunction of papillary muscles from acute ischaemia or irreversible fibrosis or necrosis (Burch *et al.*, 1963; Phillips *et al.*, 1963; Orlando *et al.*, 1964; Heikkilä, 1967, 1971; De Pasquale and Burch, 1971); (b) rupture of papillary muscle-leaflet connection (Cederqvist and Söderström, 1964; Robinson, *et al.* 1965; Morrow *et al.*, 1968); (c) ventricular wall dyskinesia (Burch *et al.*, 1971; Shelburne and Gorlin, 1972), and aneurysm with abnormal spatial relations of the papillary muscles; (d) dilatation of the mitral valve ring in ventricular dilatation (Holloway *et al.*, 1965; Friedberg, 1966); or (e) asynchronous contraction, e.g. in arrhythmias (Vandenberg *et al.*, 1969), may lead to valvar regurgitation. The inconstancy of 'ischaemic mitral regurgitation' (Heikkilä, 1967, 1971; De Pasquale and Burch, 1971) necessarily renders statements of incidence imprecise. Figures varying from 8 per cent (Yater *et al.*, 1948) to 55 per cent (Heikkilä, 1967) appear to depend upon the criteria used for selection. All patients included in this study have been investigated with a view to venous graft or left ventricular surgery; they all had severe symptoms. Therefore, this group is highly selected and does not permit conclusions about the general incidence of mitral regurgitation in coronary heart disease.

Discrepancies between auscultatory, phonographic, and angiographic findings in this study as well as in others may be explained by the variability of mitral reflux (Heikkilä, 1967, 1971; Shelburne and Gorlin, 1972). This may also hold for the varying character, intensity, and localisation of the systolic murmur. In common with other authors (Burch *et al.*, 1971; Phillips *et al.*, 1963), we have found that the 'diamond shaped' or ejection type murmur, as well as pan- or late systolic murmurs,

occurred with mitral regurgitation, but no type of murmur correlated with the grade of reflux on angiography (Heikkilä, 1967, 1971; Shelburne *et al.*, 1968; Sanders *et al.*, 1971; Shelburne and Gorlin, 1972), nor did the intensity and character of the systolic murmur strictly correspond with any particular mechanism of valvar regurgitation (De Busk and Harrison, 1969; Heikkilä, 1971). 'Silent' mitral regurgitation (Aravanis, 1965; Forrester *et al.*, 1971) has been reported, and 15 of our 39 patients with angiographically demonstrable mitral regurgitation had no murmur. However, no statement is possible as to whether mitral regurgitation was 'silent' in those patients when seen on ventriculograms because phonocardiography was not performed during angiocardiology. When mitral regurgitation could be regarded as angiographically significant (grades 2 to 4/4) a systolic murmur was usually associated (Table 1). On the other hand, the systolic murmur heard in 29 patients without angiographic evidence of reflux might have been the result of real regurgitation at the time of clinical or phonocardiographic examination. An ejection-type systolic murmur might, of course, have arisen from a minimally sclerotic aortic valve or have been associated with asynergic ventricular contraction interfering with the subvalvar mechanism.

The variability of mitral reflux depends on the mechanism of valvar regurgitation. If it is the result of transient papillary muscle ischaemia (Holmes and Logan, 1968) or reversible localised dyskinesia of the free ventricular wall from acute hypoxia (Herman *et al.*, 1967), the systolic murmur of mitral regurgitation can vary from day to day (De Pasquale and Burch, 1971). A consistent murmur, on the other hand, is highly suggestive of irreversible fibrosis or necrosis of papillary muscle structure (with or without ruptured connection to the mitral valve), or of permanent dyskinesia of the ventricular wall.

Both historically and electrocardiographically, patients with mitral regurgitation had a significantly higher incidence of previous myocardial infarction than those without mitral regurgitation. Unlike some authors (Orlando *et al.*, 1964; Robinson *et al.*, 1965; Morrow *et al.*, 1968; Heikkilä, 1971; Sanders *et al.*, 1971), but in agreement with Heikkilä (1967), we did not find a higher incidence of mitral regurgitation in patients with posteroinferior myocardial infarction than in those with anterior infarction. This distribution corresponded well with the frequency of valvar regurgitation in various patterns of coronary arterial disease. Again, the concept of a complex mechanism of

mitral closure which may be impaired at different levels of the valvar apparatus is favoured. If papillary muscle dysfunction resulting from ischaemia is the only cause of valvar regurgitation, a higher incidence of reflux from posteromedial papillary muscle dysfunction would be expected since its blood supply is more vulnerable (James, 1968). However, reflux may occur in anterolateral infarction (with or without aneurysm) because of local dyskinesia or abnormal spatial relations even with normal contraction of the anterolateral papillary muscle itself. In this context it is interesting that electrocardiographic criteria of papillary muscle infarction (Phillips *et al.*, 1963; Burch *et al.*, 1971) were rare in our series (15%) and were not useful in predicting mitral regurgitation. Nor is electrocardiographic evidence of left ventricular hypertrophy a reliable feature of ischaemic mitral regurgitation (Heikkilä, 1971) because it may be masked by myocardial infarction (Shelburne and Gorlin, 1972). Signs of left atrial enlargement on the electrocardiogram (Heikkilä, 1971) are slightly more helpful.

The findings on plain chest radiographs essentially agree with the electrocardiographic findings, i.e. a normally sized left ventricle and atrium do not preclude mitral regurgitation (Heikkilä, 1971), and moderate atrial enlargement is more strongly associated with mitral regurgitation than is left ventricular hypertrophy. Left atrial enlargement appears to be more significantly influenced by raised left ventricular end-diastolic pressure from abnormal function, rather than by volume-overload from mitral reflux, as shown in Table 2. Left ventricular impairment is significantly related to the incidence of mitral regurgitation but not to its degree (Table 1). Many authors (Sanders *et al.*, 1965; Raftery *et al.*, 1966; Heikkilä, 1971) have attributed the near normal size of the left atrium in ischaemic mitral regurgitation to low compliance of that chamber. Thus, the regurgitant pressure wave is propagated back to the pulmonary venous system with a typically high 'v' wave (Raftery *et al.*, 1966; Forrester *et al.*, 1971; Heikkilä, 1971) and the radiographic appearance of pulmonary venous hypertension may also explain that a third heart sound and a rapid filling wave are relatively uncommon findings in ischaemic mitral regurgitation. The regurgitant volume returns to the left ventricle later in diastole than in the case of a highly compliant and dilated left atrium in mitral valvar disease, which is usually associated with a third heart sound and a steep rapid filling wave.

The fact that the grade of reflux does not correspond well with the haemodynamic and angiographic grade of left ventricular dysfunction

suggests that different mechanisms of valvar regurgitation may lead to various grades of atrial opacification on ventriculography. As shown in Table 3 there was a higher incidence of localised or generalised abnormal left ventricular contraction (Heikkilä, 1971; Shelburne and Gorlin, 1972) in patients with any grade of mitral regurgitation than in those without regurgitation. Conversely, patients with abnormal left ventricular contraction, particularly those with generalised poor contraction from ischaemia, tend to have mitral regurgitation (Table 1). In this latter group left ventricular enlargement itself may interfere with mitral valve closure by abnormal spatial relations between papillary muscles and mitral leaflets (Friedberg, 1966; Hurst and Logue, 1970; Burch *et al.*, 1971).

We thank the physicians and surgeons of the National Heart Hospital for allowing us to study their patients.
