SUMMARY Systolic time intervals were measured from simultaneous high speed recordings of the electrocardiogram, phonocardiogram, and carotid artery pulse in 15 men with chronic severe anaemia not in heart failure and with a normal heart size, and in 15 normal men. Heart rates, electromechanical systole (QS2), pre-ejection period index (PEPI), left ventricular ejection time index (LVETI), and the ratio of pre-ejection period to left ventricular ejection time (PEP/LVET) did not differ significantly in the two groups.

After the intravenous administration of frusemide in 10 of the anaemic patients, the pre-ejection period index was prolonged, the PEP/LVET ratio increased, heart rate increased, and the left ventricular ejection time index shortened. Intravenous digoxin did not alter the QS2 interval and heart rate significantly in the anaemic subjects. Left ventricular function in chronic severe anaemia as measured by systolic time intervals does not differ from that of normal controls. The effect of frusemide on the systolic time intervals is explained as an effect of the fall in preload, bringing cardiac function further down on the ascending limb of the Frank-Starling curve. Other related studies are discussed.

Systolic time intervals, as measures of left ventricular performance, have been widely used.^{1,2} Alterations have been noted not only in heart failure,³ but also in the absence of clinical heart failure in subjects with diabetes mellitus,⁴ chronic alcoholism,⁵ and chronic severe anaemia.^{6,7} The findings in anaemia, however, have been conflicting, and this study was therefore undertaken to repeat them.

Subjects and methods

The study was conducted in a group of 15 men with chronic severe anaemia (haemoglobin less than 4 g/100 ml) caused by hookworm infestation, and in a control group of 15 normal men (haemoglobin more than 13 g/100 ml).

The subjects studied underwent a complete clinical examination to rule out any other relevant disease.

The systolic time intervals were measured from a simultaneous recording of the electrocardiogram, phonocardiogram, and carotid artery pulse tracing on a multichannel direct writing machine (Siemens Mingograf Cardirex 6T) at a paper speed of 100 mm per

second. The recordings were taken in the basal post-absorptive state between 9 and 11 am. All patients had a normal heart size on the chest x-ray film. None had congestive heart failure or evidence of atrioventricular or intraventricular conduction defects. All were in sinus rhythm.

The electrocardiographic lead II was used since this showed the onset of ventricular depolarisation clearly in all cases.

The phonocardiogram was recorded with a piezo-electric crystal microphone (EMI 25, Elema-Schonander) over the praecordium in a position optimal for recording the first high frequency vibrations of the second heart sound.

The carotid arterial pulse tracing was recorded over the right carotid artery in held expiration with an infraton pulse receptor (EMT 439 R Elema-Schonander). The device was held in place manually and the tracing watched on an oscilloscope, the recording being taken only when the carotid notch was clearly evident.

In 10 of the patients with anaemia, after the basal records were obtained, frusemide 80 mg was given intravenously. After two hours the amount of urine passed was noted and the recordings were repeated. During this period the patient was at rest.

Present address: Department of Medicine, Maulana Azad Medical College, New Delhi-110002 (India).

Received for publication 10 November 1980

In six of these patients the recordings were repeated after an interval of two days and digoxin 1 mg was then given intravenously. The recordings were repeated an hour later, the patient being monitored on an oscilloscope meanwhile.

The following intervals were measured directly.

(1) Total electromechanical systolic interval (QS2)—from the onset of the Q wave to the first high frequency vibrations of the second heart sound.

(2) The left ventricular ejection time—from the beginning of the upstroke of the carotid pulse to the trough of the incisura.

(3) The RR interval, for heart rate.

The pre-ejection phase was calculated by subtracting the left ventricular ejection time from QS2.

The ratio of PEP/LVET was calculated from the above values. The measurements were made on 10 consecutive beats and the mean was taken. The pre-ejection period and left ventricular ejection time were corrected for heart rate using the regression equation of Weissler *et al.*³ and the suffix (I) identifies these derived indices.

Statistically significant differences between control and anaemic subjects were assessed by Student's *t* test, but those in the anaemic subjects before and after frusemide and digoxin were assessed by the paired *t* test. The conventional level of significance ($p < 0.05$) was used.

Results

Table 1 compares the observations made in the control group with those in the anaemic group. No significant differences were observed in the heart rate, QS2 pre-ejection period index, left ventricular ejection time index, and PEP/LVET ratio. The anaemic subjects were older than the controls but age has no influence on the pre-ejection phase and left ventricular ejection time corrected for heart rate.^{8,9}

Beat to beat variability was evaluated by comparing

the pre-ejection period in a random beat with the mean pre-ejection period of 10 beats, in 10 patients. This variability was not significant statistically. We have previously established in our laboratory that measurements of the effects of such variability on systolic time intervals do not differ in statistical significance from others in the same subject when done under basal conditions on different days (unpublished data). Further evidence of the accuracy of our measurements is afforded by their return to previous basal values two to three days after the administration of the diuretic.

After the administration of frusemide, we observed a very highly significant prolongation of the pre-ejection period index and PEP/LVET ratio ($p < 0.001$), a highly significant shortening of left ventricular ejection time index ($p < 0.01$), and a significant increase in heart rate ($p < 0.05$) (Table 2). The volume of urine passed by the patients in the two hours after frusemide ranged from 600 to 750 ml.

In six of the patients to whom digoxin was given, there were no significant changes in QS2, left ventricular ejection time index, pre-ejection period index, PEP/LVET ratio, and heart rate (Table 3).

Discussion

Systolic time intervals are accepted as measures of left ventricular contractility and pump function.³ The pre-ejection period, in particular, has been shown to have a significant correlation with internally measured left ventricular dP/dt and with other indices of left ventricular performance such as cardiac index, stroke volume index, left ventricular end-diastolic pressure, and ejection fraction.¹⁰ The occurrence of left ventricular failure in chronic severe anaemia is still a matter for controversy. Some cases of congestive heart failure in uncomplicated anaemia have been reported,^{11,12} but these have been clinical descriptions unsupported by haemodynamic data.

Guleria and co-workers¹³ undertook pulmonary

function studies in patients with severe anaemia and found an increase in pulmonary capillary blood volume. This they interpreted as being the result of pulmonary congestion caused by heart failure but the rise was not statistically significant. Moreover, Rankin *et al.*¹⁴ have reported decreased pulmonary capillary blood volume in chronic anaemia.

The concept of non-cardiac circulatory congestion has been postulated by Eichna *et al.*¹⁵ and Eichna,¹⁶ who suggested that both systemic and pulmonary vascular congestion may arise on a non-cardiac basis to produce a clinical syndrome that closely simulates congestive heart failure.

Our data conclusively show that there is no left ventricular dysfunction in uncomplicated severe anaemia that can be shown by measurement of systolic time intervals. The response to the intravenous administration of frusemide further supports this contention. The pronounced prolongation of the pre-ejection period index and increase in PEP/LVET ratio after this drug shows that the heart was performing normally beforehand and was on the ascending limb of the Frank-Starling curve. Prolongation of the pre-ejection period, reduction in left ventricular ejection time, and increase in PEP/LVET ratio are known to occur with

heart failure.³ If subclinical heart failure had been present one would have expected an improvement of left ventricular function after the diuresis, manifested by shortening of the pre-ejection period. The reduction in blood volume consequent upon the diuresis must have decreased the filling pressures and the compensatory mechanisms that maintained the cardiac output. That right sided filling pressure may fall drastically with frusemide has been shown by us¹⁷ in a more recent study on comparable anaemic subjects.

In heart failure, after digoxin administration, there is shortening of all the systolic time intervals, the effect being more obvious than in normals.¹⁸ The effect on the QS2 interval is perhaps the most consistent of these changes and was not observed in our six patients.

Abdullah and co-workers⁷ also found no significant differences in systolic time intervals in patients with moderate anaemia without congestive heart failure when compared with normal controls. We have no explanation to offer for the contrary observations of Manchanda and co-workers,⁶ reporting on severely anaemic subjects, who found prolongation of the pre-ejection period alone in the presence of a normal ejection time index, since it has been shown that in heart failure total electromechanical systole is unchanged, a

prolonged pre-ejection period being associated with a shortened left ventricular ejection time.³ Certainly, in diabetics and chronic alcoholic subjects, subclinical left ventricular dysfunction has been accompanied by such findings.^{4,5}

In chronic severe anaemia the haemodynamic changes are likely to be those associated with enhanced rather than reduced ventricular function. Animal studies have shown a significant increase in contractility in dogs with dextran-induced normovolaemic anaemia¹⁹ and a shortened pre-ejection period with an increased left ventricular ejection time have been shown in patients with chronic severe anaemia,⁷ the latter change being thought to be the consequence of raised stroke volume. Our results, though not showing increased contractility, conclusively indicate that subclinical left ventricular failure does not occur in chronic severe anaemia.
