SUMMARY In nine patients with severe left ventricular failure caused by coronary artery disease or congestive cardiomyopathy, left ventricular pressure, cardiac output, coronary sinus blood flow, and myocardial substrate extraction were measured before and during infusion of sodium nitroprusside. Infusion of 55 μg/min reduced left ventricular systolic and end-diastolic pressures, peripheral resistance, coronary sinus flow, and myocardial oxygen consumption. Left ventricular minute work increased slightly, but the large improvement in myocardial efficiency was mainly the result of decreased oxygen consumption. Doubling the infusion rate to 110 μg/min caused no further decrease in ventricular pressures despite further reduction of peripheral resistance; as myocardial oxygen consumption did not change, the further improvement in efficiency was due to increased external work, the result of increased stroke volume. Thus, nitroprusside appears to improve efficiency in low dose by reducing load (ventricular pressure and volume decrease) and in high dose by increasing work at constant load.

The large reduction in coronary sinus flow during the infusion of 55 μg/min did not provoke angina or lactate production, and thus reflected decreased myocardial oxygen demand and not inadequate perfusion pressure. The improvement in efficiency during nitroprusside infusion was not accompanied by significant changes in arterial concentration, extraction ratio, or oxygen extraction ratio of any of the substrates measured, and substrate consumption fell in proportion to coronary flow. Six patients performed isometric exercise during and after nitroprusside infusion. Off nitroprusside exercise increased heart rate, systolic pressure, and peripheral resistance; end-diastolic pressure rose in five patients. Myocardial oxygen consumption increased proportionately more than work to produce a small but significant decrease in efficiency. Exercise during nitroprusside infusion did not increase heart rate and peripheral resistance significantly, but end-diastolic pressure and myocardial oxygen consumption rose substantially, causing a large reduction in efficiency. Thus, though nitroprusside improves the performance of the failing heart, the gain in efficiency is precarious, and is substantially eroded by the stress of isometric exercise.

Drugs which act primarily upon the peripheral circulation may improve the performance of the failing heart. Sodium nitroprusside is a potent venous and arterial dilator, and its rapid onset and short duration of action allow its effects to be studied during diagnostic cardiac catheterisation. The response to the drug in individual patients may predict the efficacy of oral vasodilator therapy. Previous studies demonstrate considerable variation between patients in the haemodynamic changes and the dose of nitroprusside that can be tolerated before blood pressure falls to unacceptable levels.

In general, patients with severe failure sustain the most benefit, and tolerate high doses without precipitous reduction of blood pressure. For this study we selected patients who had clinical and haemodynamic evidence of severe left ventricular failure and who might, therefore, all have similar responses to nitroprusside and tolerate the same dose. In addition, the effects of the drug were of direct relevance to the future management of each patient.

The haemodynamic effects of nitroprusside are well documented but there is less information about its effects upon myocardial oxygen consumption and substrate extraction. Measurement of myocardial
Effects of sodium nitroprusside in severe left ventricular failure

Oxygen consumption allows the estimation of myocardial efficiency,7 which from theoretical considerations8 may be useful in assessing the consequences of changes in loading conditions.

In this report we describe the effects of nitroprusside infusion at rest and during isometric exercise in patients with severe left ventricular disease, with particular reference to work, myocardial oxygen consumption, and efficiency. Myocardial lactate extraction was measured to investigate the effects of nitroprusside upon the balance between oxygen supply and demand.9 10 Extraction of other substrates was measured to determine whether changes in myocardial energy consumption and efficiency were associated with metabolic changes.

Patients and methods

Nine male patients (ages 18 to 56) were studied. All were limited by dyspnoea and had clinical evidence of severe heart failure despite treatment with bed rest and diuretics. The nature and purpose of the investigation was explained, and each patient gave written consent.

All studies were performed after an overnight fast. One hour before catheterisation atropine 0·6 mg and diazepam 10 mg were given intramuscularly, and heparin 45 units/kg was administered intravenously to minimise the effect of a subsequent dose of heparin upon free fatty acid concentrations.11 Right and left heart catheterisation was performed via the right femoral vein and artery respectively. A second dose of 45 units/kg heparin was given immediately after arterial catheterisation. After routine pressure measurements and coronary arteriography a Schwarzer Swan Ganz catheter for dye dilution cardiac output determination was positioned in the pulmonary artery, and a Telco (MM52) catheter-tip micromanometer in the left ventricle. A No. 7 Ganz catheter (Wilton-Webster Inc.) was advanced via a left antecubital vein into the coronary sinus, and its position confirmed by injection of contrast. Cold saline was injected into the right atrium to ensure that the dilution thermistor was unaffected by reflux of atrial blood.12 Left ventricular pressure, cardiac output, and coronary sinus flow were measured and left ventricular and coronary sinus blood sampled. Using a constant infusion pump, sodium nitroprusside was administered into the pulmonary artery at a rate of 55 μg/min. After allowing 15 minutes for stabilisation, measurements and samples were repeated. In seven patients the infusion rate was increased to 110 μg/min and further measurements made. In six patients the 110 μg/min infusion was continued and measurements repeated after three minutes of isometric exercise (75% maximal hand grip). The nitroprusside was stopped, and further measurements made at rest and during identical isometric exercise. Substrate concentrations were not measured during exercise because of its effect upon arterial lactate concentration.13

The micromanometer signals were displayed on a Cambridge 12 channel recorder, and analysed on line by a Varian computer (620/L-100) to yield max dP/dt and KV max. Mean systolic pressure was derived by planimetric integration of the ventricular pressure trace and used in the calculation of stroke work, minute work, and peripheral resistance. Dye dilution curves were analysed by a Schwarzer IVH 3 cardiac output computer. Coronary sinus blood flow was estimated by constant infusion thermodilution,14 and blood oxygen content measured upon a LEX O2 CON-TL. Blood samples were added to aliquots of perchloric acid for subsequent photometric estimation of lactate and pyruvate,15 acetoacetate and hydroxybutyrate16 and glycerol,17 and to sequestrene tubes for estimation of free fatty acids.18

Myocardial oxygen consumption was calculated as coronary sinus flow × arteriocoronary sinus O2 differences. Cardiac efficiency was estimated as:

LV minute work (kg m/min)×100 (Normal = 40%)

Myocardial oxygen consumption × 2·059 × 0·8067

The extraction ratio of a substrate is defined as the difference in concentration between arterial and coronary sinus blood as a percentage of arterial concentration. The oxygen extraction ratio is the oxygen that would be required for complete oxidation of the amount of that substrate extracted expressed as a percentage of measured oxygen extraction.

Statistical analysis was by Student's t test. Values are expressed as mean ± SEM (p<0·05 is considered significant).

Results

Each of the nine patients studied had evidence of severe left ventricular disease. Their angiocardiographic and basal haemodynamic results are listed in Table 1. Four had normal coronary arteriograms and were diagnosed as having congestive cardiomyopathy. The five patients with coronary artery disease were limited by dyspnoea rather than by angina.

The effects of nitroprusside administration are shown in Fig. 1 and 2. Infusion of 55 μg/min significantly reduced peak left ventricular systolic pressure from 93±5 mmHg to 81±3 mmHg (p<0·01), end-diastolic pressure from 23±2 mmHg to 11±3 mmHg (p<0·01), and peripheral resistance from 31±4 units to 25±4 units (p<0·01). The changes in heart rate from 107±7 to 106±7 beats/min, KVmax from 78±4/s to 65±7/s, and max dP/dt from 888±88 mmHg/s to 849±59 mmHg/s were not

EF, ejection fraction; EDVI, end-diastolic volume index (ml/M²); CI, cardiac index (1/min per M²); LVEDP, left ventricular end-diastolic pressure (mmHg); PR, peripheral resistance (units); MVO₂, myocardial oxygen uptake (ml/min); LVMW, left ventricular minute work (kg m/min).

*Sternal angle used as zero reference for all pressure measurements.

significant. Cardiac output increased from 2.87±0.36 l/min to 3.32±0.44 l/min (p<0.05), and left ventricular minute work from 2.16±0.34 kg m/min to 2.52±0.32 kg m/min (p<0.01). There were substantial reductions in coronary sinus flow, from 195±19 ml/min to 139±12 ml/min (p<0.01) and myocardial oxygen consumption from 22.5±2.8 ml/min to 14.2±1.2 ml/min (p<0.01), and efficiency increased from 6.4%±1.1% to 11.5%±1.8% (p<0.01).

In seven patients increasing the infusion rate of nitroprusside to 110 µg/min did not change left ventricular systolic or end-diastolic pressure significantly though there was further reduction of peripheral resistance from 25±4 to 18±4 units (p<0.02). Cardiac output increased further from 3.32±0.44 l/min to 4.23±0.61 l/min (p<0.01) and left ventricular minute work from 2.52±0.32 kg m/min to 3.15±0.5 kg m/min (p<0.01). The changes in coronary sinus flow, from 139±12 ml/min to 142±14 ml/min, and myocardial oxygen consumption...
Effects of sodium nitroprusside in severe left ventricular failure

from 14.2±1.2 to 13.4±1.4 ml/min were not significant. Efficiency increased further from 11.5%±1.8 to 16.0%±3.1 (p<0.05). Heart rate, 107±7 and 106±6 beats/min, KVmax, 65±7 and 57±8/s, and max dP/dt, 849±56 and 891±72 mmHg/s were similar at both infusion rates.

The effects of isometric exercise in six patients are illustrated in Fig. 3. Off nitroprusside, exercise increased heart rate from 94±4 to 114±7 beats/min (p<0.02), left ventricular systolic pressure from 99±4 mmHg to 112±7 mmHg (p<0.05), and peripheral resistance from 26±5 units to 33±5 units (p<0.02). Cardiac output changed little, and the increase in left ventricular minute work from 2·38±0.20 kg m/min to 2·70±0.27 kg m/min was not significant. Coronary sinus flow increased from 168±18 ml/min to 250±42 ml/min (p<0.05) and myocardial oxygen consumption from 18·3±3·3 ml/min to 27·5±4·8 ml/min (p<0.05). There was a small, but significant decrease in efficiency from 8·5%±0·9 to 6·9%±1·2 (p<0.05). Max dP/dt increased from 880±38 to 982±51 mmHg/s (p<0.05), and KVmax from 73±4 to 84±9/s (NS). When isometric exercise was performed during nitroprusside infusion at 110 µg/min the increase in heart rate from 100±4 to 109±8 beats/min was not significant. Left ventricular systolic pressure increased from 78±7 mmHg to 87±2 mmHg (p<0.05) and end-diastolic pressure from 9±3 mmHg to 18±4 mmHg (p<0.05). Cardiac output changed from 4·59±0·63 l/min to 4·41±0·75 l/min, peripheral resistance from 18·4±5 units to 21·2±5 units, and left ventricular minute work from 3·63±0·35 kg m/min to 3·17 kg m/min: these were not significant. The small increases in KVmax, 63±6/s to 68±7/s, and max dP/dt, 843±72 mmHg/s to 864±86 mmHg/s, were not significant. Coronary sinus blood flow increased from 147±24 ml/min to 214±34 ml/min (p<0.02) and myocardial oxygen consumption from 12·7±2·4 to 19·8±3·6 ml/min (p<0.01), and efficiency decreased from 19·5%±3·2 to 11·2%±2·5 (p<0.05).

The patterns of response to nitroprusside, both at rest and on exercise, were similar in patients with cardiomyopathy and coronary artery disease.
The effects of nitroprusside infusion upon myocardial substrate extraction are summarised in Table 2. Drug administration was without significant effect upon the arterial concentration, extraction ratio, or oxygen extraction ratio of any of the substrates measured. Of the five patients with coronary artery disease, one was producing lactate in the control period (extraction ratio −5.5%), but during nitroprusside infusion extraction ratio rose to +6.5%. Despite the pronounced fall in coronary sinus flow, nitroprusside did not provoke lactate production or angina in any of the patients with coronary artery disease. At the highest dose of nitroprusside, however, one patient with congestive cardiomyopathy produced lactate (ER −2%). This was not associated with angina or electrocardiographic abnormalities. The total of the oxygen extraction ratios was similar before and during both infusion rates of nitroprusside, 113%±13, 118%±21, and 146%±33.

Discussion

Sodium nitroprusside relaxes vascular smooth muscle, and as it has no direct effect upon the myocardium, changes in cardiac performance during its administration are the result of alteration of loading conditions. Muscle tension, which depends upon both ventricular pressure and volume, is the load opposing myocardial contraction. As muscle tension changes throughout systole its mean value may be the best measure of load in the intact ventricle, and myocardial oxygen consumption will relate closely to load so defined. At constant heart rate and inotropic state the direction of change in tension can be inferred from changes in ventricular systolic and diastolic pressures, and in myocardial oxygen consumption.

Load is not determined in a simple way by arterial or venous tone. For example, the fall in ventricular systolic pressure, and hence load, caused by a given reduction of peripheral resistance will depend upon the resulting change in stroke volume. In addition, the change in cardiac performance consequent upon load reduction will depend upon the initial load.

Thus, the effect of vasodilators upon the heart is not readily predictable. For this reason we studied only patients with severe heart failure and gross ventricular dilatation, and found that each patient had a similar response to nitroprusside.

Infusion of 55 μg/min of nitroprusside reduced left ventricular systolic and end-diastolic pressure and myocardial oxygen consumption without significant change in heart rate or indices of contractility, which suggest that load decreased. Venous relaxation, which redistributes blood volume away from the heart, is the likely explanation for the large reduction in end-diastolic pressure. Despite this fall there was a small, but significant increase in output. When the infusion rate was doubled to 110 μg/min, heart rate and indices of contractility did not change significantly. There were only minor, insignificant further reductions in ventricular pressures and myocardial oxygen consumption, suggesting little, if any, further decrease in load, despite significant further reduction in peripheral resistance. Stroke volume increased substantially. These results illustrate two apparently different mechanisms by which nitroprusside improves the performance of the failing heart: a reduction of load and energy requirements with little gain in output at the lower dose, and increased stroke volume at constant load at the higher dose.

Although there was dose-dependent reduction of peripheral resistance by nitroprusside, ventricular...
Effects of sodium nitroprusside in severe left ventricular failure

Effects of sodium nitroprusside in severe left ventricular failure

Pressure and load did not decrease further at the higher infusion rate. Peripheral resistance is the ratio of mean pressure to mean flow, and describes inadequately an arterial system in which the relation between pressure and flow depends upon resistance, capacitance, and the inertia of blood. When arterial resistance and capacitance are manipulated separately, reduction of resistance increases flow and decreases pressure, whereas increasing capacitance raises stroke volume by augmenting late systolic flow, with little effect upon pressure. In both cases calculated peripheral resistance falls, but only in the former do pressure and load decrease substantially. It is implicit in these observations that stroke volume depends upon both the load opposing contraction and the properties of the arterial system. Our results suggest that the large increase in stroke volume at the higher dose of nitroprusside was the result not of decreased load, but of a favourable change in arterial properties allowing greater ejection at the same mean load. Aortic impedance may describe arterial properties in a way that clarifies their effect upon ventricular performance. Nitroprusside reduces aortic impedance, though in circumstances where pressure has fallen rather than flow has increased.

The effect of sodium nitroprusside upon cardiac energetics can be examined by using Bing’s method of estimating the overall efficiency of the heart, which relates external work to myocardial oxygen consumption. While there are objections to this method, the oxygen cost of external work is of clinical importance. External work does not determine myocardial oxygen consumption, but the two are related in the normal heart because a fairly constant proportion of wall tension is transformed into external work by the large reduction of cavity dimensions during systole. In our patients the pressure component of work (mean systolic pressure minus end-diastolic pressure) was similar in the control state and at each dose of nitroprusside, so that changes in stroke volume determined changes in external work. The oxygen cost of developing this pressure was reduced by nitroprusside because of decreases in ventricular volume and the absolute values of pressure. The gain in efficiency at the low dose was the result mainly of this reduction in myocardial oxygen consumption, whereas the further improvement at the higher dose was because of the increased external work consequent upon greater stroke volume.

Efficiency so defined bears a complex relation to load: it is maximum at intermediate loads, falling steeply at high and low loads. In order to remain efficient in different circumstances the normal heart maintains load within reasonable limits. The steep slope relating stroke volume to filling pressure, the Anrep effect, and increased contractility all prevent dilatation and hence excessive load. In normal subjects isometric exercise increases heart rate, myocardial contractility, arterial pressure, and cardiac output without change in peripheral resistance. The increase work is performed at constant end-diastolic pressure. Myocardial oxygen consumption and external work increase in proportion so that efficiency does not decrease. In our patients the haemodynamic changes during isometric exercise when off nitroprusside were similar to those reported previously in patients with heart failure, peripheral resistance increased and end-diastolic pressure rose in five of the six. Myocardial oxygen consumption increased proportionately more than external work, so there was a small, but significant decrease in efficiency. When exercise was performed during nitroprusside infusion myocardial oxygen consumption increased substantially even though heart rate and peripheral resistance did not increase significantly, and there was only a small increase in systolic pressure. Though isometric exercise may decrease ventricular distensibility, the large rises in end-diastolic pressure and oxygen consumption suggest that the ventricle dilated in response to exercise. External work decreased insignificantly, and efficiency fell by nearly half. Thus, though initially higher on nitroprusside, efficiency decreased proportionately more during exercise than before the drug. These results show how precarious and sensitive to increased load is the improvement in efficiency caused by nitroprusside.

Conflicting results have been reported of the effects of nitroprusside upon myocardial ischaemia in patients with coronary artery disease. The large reduction in coronary flow during infusion of 55 μg/min of nitroprusside did not provoke angina or lactate production in any patient, suggesting that it reflected decreased myocardial oxygen demand rather than inadequate perfusion pressure. The resting lactate production observed in one patient with coronary artery disease was abolished by nitroprusside infusion. It is unlikely, however, that the haemodynamic improvement during drug administration in the patients with coronary artery disease was the result of relief of ischaemia, as only one of them had metabolic evidence of ischaemia at rest, and comparable haemodynamic improvement was seen in the patients with congestive cardiomyopathy, each of whom had a high basal lactate extraction ratio.

One patient with cardiomyopathy produced lactate at the higher dose, but the significance of this is uncertain, as it was not associated with pain, electrocardiographic abnormalities, or haemodynamic deterioration.
Nitroprusside caused no change in the extraction, extraction ratio, or oxygen extraction ratio of any substrate measured. The relation between oxygen uptake and substrate consumption did not change, and reduced substrate requirement was met by decreased coronary flow rather than by reduced extraction. The large improvements in efficiency were not associated with metabolic changes.

This study shows that nitroprusside has beneficial effects upon both stroke volume and myocardial energy requirements in patients with severe heart failure. At the lower dose the major effect was reduction of load and hence myocardial oxygen consumption, whereas at the higher dose stroke volume increased with little further change in load.
