Effects of vasodilator treatment with felodipine on haemodynamic responses to treadmill exercise in congestive heart failure

SUMMARY Treatment with vasodilators in heart failure has not always produced a useful improvement in the haemodynamic responses to exercise, and in many cases early drug tolerance has further limited the potential of this type of treatment. In a study to evaluate the efficacy of felodipine, a new calcium antagonist with selective vasodilator properties, in the management of congestive heart failure 10 patients with congestive heart failure underwent treadmill exercise testing before and during oral treatment with felodipine 30 mg daily. At every level of exercise felodipine lowered the pulmonary capillary wedge pressure, whereas cardiac index and stroke index increased considerably. The haemodynamic improvement was associated with an increase in the duration of exercise to exhaustion. Importantly, these beneficial effects were sustained throughout four weeks of treatment without evidence of drug tolerance. These observations suggest a useful role for felodipine in the long term management of congestive heart failure.

In patients with chronic congestive heart failure exercise related fatigue and dyspnoea are the commonest and most troublesome symptoms. The reduced capacity of the failing heart to increase output to meet the metabolic demands of working muscle and the exaggerated rise in left atrial pressure largely account for these symptoms. A critical evaluation of specific anti-failure treatment must, therefore, examine the influence it has on the haemodynamic responses to exercise. An additional consideration is the long term efficacy of treatment. This is more difficult to assess since the natural history of congestive heart failure involves a variably progressive deterioration in left ventricular function which is not easily distinguished from the development of drug tolerance.

Despite the widespread use of vasodilator agents in congestive heart failure considerable uncertainty still exists concerning the effects of these agents on the haemodynamic responses to exercise and on maximal exercise capacity.1 Moreover, the long term efficacy of vasodilators has been questioned in several reports.2-4 In the present study we examined these issues using felodipine, a new calcium antagonist with selective vasodilator activity.5-6 Calcium antagonists have not previously been evaluated in the outpatient management of congestive heart failure. Beneficial haemodynamic and metabolic responses have, however, been shown when felodipine is given acutely to patients with severe heart failure.7-8 We report the effects of felodipine on the haemodynamic responses to treadmill exercise during long term treatment.

Patients and methods

PATIENT SELECTION
Ten patients (nine men and one woman, age range 38-66 years) were studied (Table 1). All were selected on the basis of moderate to severe congestive heart failure which was symptomatic (New York Heart Association functional class II and III) despite treatment with diuretics. Five were receiving digoxin. Cardiac catheterisation performed within 12 months of the study had confirmed impaired left ventricular function in every case with a mean (SEM) angiographic ejection fraction of only 23(2)%. Five of the group had three vessel coronary artery disease and the remainder congestive cardiomyopathy of unknown aetiology. The patients were all in stable sinus rhythm. Written informed consent was obtained from

each patient before inclusion in the study.

STUDY PROTOCOL

All vasodilator treatment was stopped at least four days before the study. Treatment with digoxin and diuretics was maintained throughout the 30 days of the study, although in two cases a small reduction in diuretic dosage was necessary after the introduction of felodipine. Exercise studies were always performed between 1600 and 1700 h after a four hour fast. The morning dose of diuretics and other regular medications was not withheld. Each patient underwent a total of five exercise tests. The first, a preliminary test, permitted an assessment of maximal exercise capacity and was performed without invasive haemodynamic measurements. On day 1 of the study control haemodynamic data during exercise were obtained after which treatment with oral felodipine 10 mg three times a day was started. Further exercise tests were performed after two days and four weeks of treatment (days 3 and 28 respectively). After day 28 felodipine was withdrawn, and placebo tablets were substituted. Two days later (day 30) the final exercise test was performed. Plasma samples for felodipine assay were obtained immediately before exercise testing on each of the study days.

EXERCISE TESTS
Heart rate was monitored from a precordial lead. Arterial blood pressure was recorded from a cannula placed in the radial artery. A balloon tipped thermodilution catheter placed in the pulmonary artery was used to monitor pulmonary capillary wedge pressure and cardiac output (measured in duplicate using 10 ml of iced saline). All pressures were measured in the upright posture with reference to the mid-chest. Arterial and mixed venous samples for gas analysis were drawn from the radial artery and the pulmonary artery respectively within one minute of the cardiac output measurements. Blood oxygen content, arteriovenous oxygen difference, systemic oxygen consumption index, and derived haemodynamic variables were calculated using standard formulas.

All patients were exercised on a treadmill. The Bruce protocol was used in eight patients and the less demanding Naughton protocol in two, both of whom had severely reduced exercise capacity. The same exercise protocol was used throughout the study in individual patients. Once maximal exercise capacity had been established in the preliminary test an arbitrary 75% submaximal level was calculated. In all subsequent exercise tests haemodynamic measurements were made at rest (resting 1), after two minutes of exercise, at submaximal exercise, and at maximal exercise. A final set of measurements was made during recovery (resting 2), one minute after maximal exercise. Blood samples for gas analysis were drawn at rest and at submaximal exercise. In individual patients the same level of submaximal exercise was used in each test to provide a directly comparable set of data. Values are expressed as mean (standard error of mean (SEM)).

STATISTICAL ANALYSIS
Analysis of variance was used to test the overall significance of the changes at each level of exercise during the course of the study. Those variables which

Results

Table 2 summarises the haemodynamic responses to treadmill exercise before, during, and after long term treatment with felodipine. Figure 1 shows the effects of felodipine on individual haemodynamic variables and on whole body oxygen utilisation at submaximal exercise.

CONTROL DATA (DAY 1)
Though the resting pulmonary capillary wedge pressure in the supine position was increased at 17 (3) mm Hg it fell to 9 (4) mm Hg on standing. The resting erect values for cardiac index (1.9 (0.1) l/min/per m²)

![Graphs showing haemodynamic responses to exercise](http://heart.bmj.com)
and stroke volume index (20(1) ml/beat/per m²), however, both showed pronounced reductions below the normal range. The mean duration of exercise to exhaustion was 7-2(0-5) minutes (Table 3). During exercise, pulmonary capillary wedge pressure rose steeply to 26(5) mm Hg at peak exercise, whereas cardiac index and stroke volume index rose to only 5-2 (0-5) 1/min/per m² and 37(3) ml/beaat/per m² respectively (Fig. 2). Considerable increments in arteriovenous oxygen difference and systemic oxygen consumption index were also noted.

FELODIPINE TREATMENT (DAYS 3 AND 28).
Felodipine treatment produced a rapid improvement in both resting and exercise haemodynamics, which was sustained throughout the four week treatment period. The mean duration of exercise increased by 24% (Table 3). The pulmonary capillary wedge pressure was lower at rest and at every level of exercise and never exceeded 16 (4) mm Hg. Cardiac index and stroke volume index also improved considerably during this period rising to 6-7(0-6) 1/min/per m² and 48 (4) ml/beat/per m² respectively at maximal exercise. Blood pressure at rest and during exercise and systemic vascular resistance were also significantly reduced but heart rate was unaffected by felodipine treatment (Fig. 2). These beneficial haemodynamic effects were associated with a pronounced decline in the arteriovenous oxygen difference, although systemic oxygen consumption index remained unchanged (Fig. 1). Plasma felodipine concentrations on days 3 and 28 of the study were similar (Table 3).

PLACEBO (DAY 30)
Two days after felodipine withdrawal plasma concentration had fallen to 5-8(0-9) nmol/l, and a pronounced deterioration in the rest and exercise haemodynamic variables was seen. Cardiac index and stroke volume index fell considerably and were not significantly different from the control values. Nevertheless, despite an increase in the pulmonary capillary wedge pressure above the treatment levels it remained significantly lower than control values during exercise (Fig. 2). The mean duration of exercise to exhaustion remained close to the level achieved during felodipine treatment (Table 3).

DRUG RELATED SIDE EFFECTS
Felodipine was generally well tolerated. Two patients reported some postural dizziness early during treatment. In both cases a small reduction in diuretic dosage was made, and the symptoms subsided within three days. A third patient developed mild non-cardiac ankle oedema during treatment.

Discussion
These data show that felodipine treatment in congestive heart failure is well tolerated and improves the haemodynamic responses to treadmill exercise. The haemodynamic improvement is associated with an increase in exercise tolerance. Importantly, both effects are sustained during four weeks' treatment without evidence of tachyphylaxis.

Several short term clinical studies have shown that the vasodilator properties of calcium antagonists can improve left ventricular function in patients with congestive heart failure.10-12 Enthusiasm for this approach, however, has been tempered by reports of pulmonary oedema and circulatory collapse during treatment with these compounds13-15 due presumably to an adverse effect on myocardial contractility.16,17 For this reason calcium antagonists are not at present widely used in heart failure. Nevertheless, the recent introduction of felodipine, a nifedipine analogue with pronounced vascular selectivity, promises to extend the clinical application of this class of agents. Experimental work has shown that felodipine is a potent vasodilator with negligible effects on the myocardium.5,6 Short term clinical studies confirm that the drug is without detectable negative inotropic properties.8,18 This distinguishes felodipine from other currently available calcium antagonists and suggests that the drug might be used safely in patients with congestive heart failure. The data we have presented support this suggestion.

The patients included in this study all had severe left ventricular dysfunction. Adequate diuretic treatment ensured that the resting pulmonary capillary wedge pressure in the upright posture was normal, although cardiac output was considerably reduced. The responses to treadmill exercise were typical for patients of this type.19,20 An attenuated increase in cardiac output was seen despite a rapid and exaggerated rise in pulmonary capillary wedge pressure. Exercise capacity, therefore, was reduced because of the early onset of fatigue and dyspnoea.

The vasodilator properties of felodipine lowered blood pressure and systemic vascular resistance at rest and produced a substantial increase in cardiac output. Heart rate was unaffected indicating that the improvement in cardiac output was due entirely to an increase in stroke volume. The improvement in stroke volume will itself have tended to reduce the pulmonary capillary wedge pressure.31 Our data, however, do not exclude simultaneous drug induced venous pooling even though calcium antagonists usually have relatively little effect on the capacitance vessels.32 Similar beneficial effects were apparent during exercise. Thus at every level of exercise the pulmonary capillary wedge pressure was lower and the cardiac
Felodipine during exercise in heart failure

index was higher with felodipine. Consequently, exercise capacity increased considerably. That the haemodynamic improvement was a direct result of the drug intervention is confirmed by the fact that felodipine withdrawal led to a sharp reduction in plasma concentrations associated with a rapid deterioration in left ventricular function towards the baseline level.

Previous investigations of vasodilator treatment in congestive heart failure have shown a similar improvement in cardiac output at submaximal exercise, but reductions in left ventricular filling pressure usually occur only with drugs such as nitrates and prazosin, which have venodilator activity. Importantly, however, these studies have not always been able to show improvement in these haemodynamic variables at maximal exercise. In this respect, therefore, felodipine appears to have advantage over some of the currently available vasodilators since useful effects on both the filling pressure and the output of the left ventricle were seen both at submaximal and at maximal exercise.

In the present study a four week treatment period was used to evaluate the long term efficacy of felodipine. Although relatively short, this period was chosen in order to minimise the confounding influence of deteriorating left ventricular function on the data interpretation. The findings show that both the plasma concentrations and the beneficial haemodynamic effects of felodipine are sustained, and tolerance to the drug does not occur. This represents an additional advantage of felodipine since early tachyphylaxis has been reported with several other vasodilators used for the treatment of heart failure. Prazosin, in particular, is subject to tolerance within the first several doses, although the clinical significance of this phenomenon remains uncertain and recent studies have been able to demonstrate long term efficacy.

The increase in exercise cardiac output produced by felodipine was reflected by a significant reduction in the arteriovenous oxygen difference measured at submaximal exercise. Systemic oxygen consumption, however, was unaffected at this level of exercise suggesting that the regional perfusion of working skeletal muscle did not rise appreciably in response to treatment. It must be recognised that our data provide no information on oxygen consumption at the substantially higher level of peak exercise which was achieved during felodipine treatment. Despite this the findings bear some similarity to those reported with other vasodilators and indicate that the drug induced rise in cardiac output at submaximal exercise may be directed principally to the cutaneous and visceral circulations rather than to skeletal muscle. Flow redistribution of this type has been reported during treatment with glyceryl trinitrate in the exercising rat.

The sensitivity of systemic oxygen consumption as a measure of regional skeletal muscle flow is uncertain, but it is conceivable that local metabolic factors produce maximal dilatation of muscular arterioles during exercise such that pharmacological intervention is relatively more active elsewhere in the circulation. Thus the principal benefit of felodipine treatment during exercise might relate to attenuation of the rapid rise in left ventricular filling pressure rather than to the increase in cardiac output. Indeed, this might be true of other vasodilators, and recent work has shown that long term treatment with hydralazine—a predominantly arteriolar dilator with little effect on venous tone—is no more effective than placebo in improving exercise tolerance in patients with heart failure.

Further support for the primary importance of reduced left ventricular filling pressure as mediator of the beneficial effects of felodipine treatment is provided by the changes in maximal exercise tolerance seen in the present study. Thus the haemodynamic improvement that occurred in response to felodipine was reflected by a considerable increase in maximal exercise capacity, which was sustained throughout the treatment period. Of particular interest, however, was the finding that exercise capacity showed no significant reduction two days after felodipine withdrawal despite a pronounced haemodynamic deterioration. This might, of course, reflect an exercise training effect, but the haemodynamic deterioration was manifested principally by a reduction in stroke volume which was not significantly different from control values. Pulmonary capillary wedge pressure, on the other hand, remained appreciably lower than the control value, presumably as a result of residual felodipine activity in the circulation. Thus the sustained improvement in exercise capacity after felodipine withdrawal was likely to have been due, at least in part, to persisting reduction of the left ventricular filling pressure.

Previous investigation has shown beneficial haemodynamic and metabolic responses to acute felodipine treatment in patients with severe congestive heart failure. The present study has confirmed that similar effects are sustained during long term treatment and are associated with improvement in exercise tolerance. Felodipine has several advantages over currently available vasodilators and is potentially a useful agent for the long term management of congestive heart failure.
