Unusual left ventricular wall motion and a loud added sound during the isovolumic relaxation period in a patient with hypertensive heart disease

Yuichiro Mishiro, Takashi Oki, Nobuo Fukuda

Abstract
A 69 year old woman with hypertensive heart disease had a loud added sound which coincided with a sudden interruption of the early diastolic motion of the left ventricular posterior wall, as visualised by M mode echocardiography, and came just before early diastolic transmural flow, as measured by a pulsed Doppler echocardiogram. Early diastolic motion velocity from the base to the middle of the posterior wall, assessed by pulsed Doppler tissue imaging, was markedly high and sharp, and its peak coincided with the sound. A notch, similar to that in the posterior wall motion, occurred in the left ventricular pressure curve during early diastole. No intraventricular flow signal was detected during the isovolumic relaxation period, as measured by pulsed and colour Doppler imaging. The added sound was probably produced by impact between the dilated heart, with a relaxation abnormality, and the extracardiac structures during the isovolumic relaxation period.

Keywords: added sound; abnormal relaxation; hypertensive heart disease; echocardiography

Added (extra) sounds during early diastole include a mitral opening sound and a pericardial knocking sound, as well as a third heart sound. However, it is very rare to find these heart sounds during the isovolumic relaxation period. We report here a patient with hypertensive heart disease, left ventricular systolic dysfunction, and complete left bundle branch block in whom an added sound was heard during the isovolumic relaxation period.

Case report
The patient was a 69 year old woman who had been treated for hypertension by her family doctor. In May 1995, she began to experience precordial chest pressure and she was treated with sublingual glyceryl trinitrate. When this symptom became frequent and was accompanied by dyspnoea, she again consulted her doctor and a diagnosis of congestive heart failure was made, based on a finding of pulmonary congestion on a chest radiograph. She was referred to our hospital for further investigation.

Physical examination showed a heart rate of 88 beats/min and regular, and blood pressure of 170/78 mm Hg. On auscultation, reversed splitting of the second heart sound and an added sound during early diastole, similar to the third heart sound, were heard at the cardiac apex. A systolic ejection murmur, grade 2/6 by the Levine classification, was also heard at the left sternal border in the third and fourth intercostal spaces. The liver was not palpable, and no lower extremity oedema was noted. The heart appeared enlarged, with a cardiothoracic ratio of 62%, and pulmonary congestion was noted on chest radiograph. Electrocardiogram showed normal sinus rhythm with slightly prolonged PR interval (200 ms), poor R wave progression in leads V1–V3, and complete left bundle branch block with left axis deviation (−40°) and a prolonged QRS interval (150 ms).

Phonocardiography showed a decrease in the first heart sound, reversed splitting of the second heart sound, and a low pitched added sound at the cardiac apex during early diastole (fig 1). This added sound did not change dur-

Figure 1 Phonocardiogram: the first heart sound (1) is decreased, and the second heart sound (2) indicates reversed splitting; a loud low pitched extra sound (ES) is observed at the cardiac apex during early diastole. L, M1, M2, and H: low, medium low, medium high, and high frequency phonocardiograms, respectively; 3L: third left intercostal space; P and A: pulmonary and aortic valve components of the second heart sound, respectively; ECG, electrocardiogram.
ing respiration. A systolic ejection murmur, consistent with Levine grade 2/6, also was recorded from the cardiac apex to the left sternal border in the third intercostal space.

An M mode echocardiogram showed left ventricular enlargement (end diastolic diameter 7.0 cm, end systolic diameter 5.7 cm), a decrease in percent fractional shortening of the left ventricle (23%), and left atrial enlargement (5.0 cm). There was no evidence of heart valve or pericardial disease. On simultaneous recordings using phonocardiogram, M mode, and pulsed Doppler echocardiogram, this added sound coincided with a sudden interruption of the early diastolic motion of the left ventricular posterior wall and an initial phase of abnormal forward movement of the anterior leaflet of the mitral valve during early diastole, and came just before the early diastolic transmitral flow, consistent with the isovolumic relaxation period (fig 2).

Pulsed Doppler tissue imaging showed that the early diastolic motion velocity from the base to the middle of the left ventricular posterior wall was markedly high and sharp, and its peak coincided with the added sound (fig 3, top). A coronary angiogram showed a 50% stenosis of the circumflex branch of the left coronary artery. On left ventriculography there was diffuse hypokinesia of the left ventricular wall with a left ventricular ejection fraction of 45% and abnormal inward movement of the left ventricular posterior wall during early diastole, as detected by M mode echocardiography. The left ventricular pressure curve showed a gradual decline from the isovolumic relaxation period to mid-diastole, indicating a left ventricular relaxation abnormality, and a notch during early diastole, probably corresponding to the occurrence of the added sound (fig 3, bottom). The left ventricular end diastolic pressure was 17 mm Hg. During her hospital admission, the patient’s symptoms and pulmonary congestion were improved with diuretics and vasodilators, but the added sound did not disappear on follow up examinations.

**Discussion**

Added sounds during early diastole have been reported in patients with various types of heart disease. The third heart sound and mitral opening sound are representative examples of such sounds. Added sounds are very rare in patients without heart valve disease or pericardial disease, and are most likely to occur with dilated failing hearts. In the patient described here, this sound occurred before the opening of the mitral valve, that is, during the isovolumic relaxation period, and was distinct from the third heart sound or mitral opening sound.

Added sounds during the isovolumic relaxation period may be caused by abnormal blood flow or by extracardiac factors. Lee et al have reported a patient with an added sound caused by intraventricular blood flow during the isovolumic relaxation period, and speculated that the mechanism for this sound was a prolongation of the isovolumic relaxation period with asynchrony of relaxation. Sasson et al proposed that asynchrony of contraction of the left ventricular wall at end systole may result in regional pressure differences within the ventricular cavity during early diastole, and thus lead to intraventricular blood flow during the isovolumic relaxation period and produce added sounds. Our patient had impaired left ventricular systolic function, similar to that reported by Lee et al with prolongation of the isovolumic relaxation period accompanied by a curious pattern of left ventricular posterior wall motion and an abnormal pressure curve. However, no distinct intraventricular blood flow signal was detected during
the phase corresponding to the added sound, even on detailed examination using pulsed and colour Doppler imaging.

Bonneter et al. have reported an added sound in a patient with a pericardial effusion, and have postulated that this sound was produced by impact between the heart and the pericardium or chest wall during early diastole, resulting from pendular motion due to the pericardial effusion. Ichiyasu et al. also have reported that left ventricular deviation caused by marked elevation of the diaphragm generated added sounds associated with extracardiac structures in a patient with massive ascites. These reports suggest that these added sounds are caused by impact between an enlarged or deviated heart and the extracardiac structures. In our patient, the area of the left ventricle which is adjacent to the chest wall and diaphragm is presumed to be larger than normal because of marked cardiomegaly. The motion velocity of the left ventricular posterior wall was markedly large and sharp during early diastole, and its peak coincided with the added sound. In addition, the absence of intraventricular blood flow during the isovolumic relaxation period suggests that in this case the added sound was also caused by extracardiac factors.

Rahko et al. and Shaver et al. have stated that left ventricular systolic function is more impaired when dilated cardiomyopathy is accompanied by complete left bundle branch block. Furthermore, Xiao et al. have reported that prolongation of both the isovolumic contraction period and the isovolumic relaxation period shortens the diastolic period, thus impairing left ventricular filling. Since our patient also had a dilated failing heart, this complication of complete left bundle branch block may have greatly influenced left ventricular haemodynamics and produced wall motion abnormalities. Therefore, the occurrence of added sounds may be influenced by atrioventricular conductance disturbances in addition to the ventricular relaxation abnormality.

In summary, we described a case with hypertensive heart disease producing unusual motion of the left ventricular posterior wall, and a loud added sound during the isovolumic relaxation period. This sound may have been produced by impact between the dilated failing heart, with a ventricular relaxation abnormality, and the extracardiac structures during the isovolumic relaxation period.
