Lesions I don’t stent

Clive A Layton

Ten years have passed since the concept of stenting coronary arteries became a practical reality.\(^1\) During that time the technique has evolved with improvements in technology, stent design, the design of delivery systems, selection of suitable lesions and technique. Lastly there has been a change in the perceived need for anticoagulation.\(^2\)

Contraindications have evolved in parallel with these developments. Whereas stenting for any indication other than an angioplasty disaster was exceptional, results of observational studies\(^3\) and randomised trials\(^4\) have led to a reappraisal. Indications have broadened so that many units use stents in 50% or more of angioplasties. Conservative units with stenting rates of 20% or less find it increasingly difficult to justify their reluctance to stent.

Factors previously considered as contraindications to stenting, such as large branches, long lesions, lesions on sharp bends, and increased risk of anticoagulants are no longer considered to be so significant. Even the left main stem is no longer immune from stenting as a bailout procedure, even when not protected by one or more bypass grafts. Wire stents can be used on sharp bends or to cover large side-branches and in the left main stem. Longer stents allow a range of lengths to be covered. Greater awareness of the role of antiplatelet agents, including IIb/IIIa receptor inhibitors, has reduced the risk of subacute stent occlusion and haemorrhage. Lesions in vessels where the approach to the site of the stenosis is extremely tortuous continue to present a challenging problem but improvements in delivery system design and the use of stiffer wires to straighten the target vessel temporarily make these lesions more amenable, and the contraindication is now relative rather than absolute.

I define only two categories as absolutely unsuitable for stenting. First, lesions that cannot be predilated, identified by persistent indentation during predilatation at whatever pressure is applied. These lesions, if stented, continue to show indentation of the stent, which can be confirmed using intracoronary ultrasound, and the risk of subacute occlusion is high. It is important to distinguish these lesions from those in which the balloon indentation disappears during predilatation but angiography immediately afterwards shows the stenosis to remain because of recoil. These lesions will respond well to stenting. Second, lesions in vessels smaller than 2.5 mm diameter are not stented because of the incidence of thrombosis and restenosis.
