Antegrade transcatheter closure of coronary artery fistulae using vascular occlusion devices

C A C Pedra, J Pihkala, D G Nykanen, L N Benson

Abstract

Two children (a 9 year old boy and a 2.5 year old girl) with coronary artery fistulae communicating with the right ventricle underwent successful transcatheter occlusion using an antegrade technique. A Rashkind double umbrella device was used in one case and an Amplatzer duct occluder in the other.

Coronary artery fistulae are uncommon heart lesions, but they are the most frequent significant haemodynamic congenital coronary anomaly.1 Large fistulae generally require closure to prevent complications such as myocardial ischaemia from a steal phenomenon, endocarditis, and potential aneurysmal dilatation and rupture.2 There have been many reports describing catheter based treatments as options in the management of this disorder.3–6

We report two cases in which uncommon transcatheter approaches were used to close such fistulae arising from the right coronary artery.

Case 1

A 9 year old boy was referred to our unit with a diagnosis of a coronary artery fistula. The patient was asymptomatic and physical examination was notable for a grade 3/6 continuous murmur heard at the left lower sternal border. The resting ECG and chest radiograph were normal. Echocardiography showed a mildly dilated ventricle. A fistula was seen by colour Doppler arising from a dilated right coronary artery (RCA) and draining into the right ventricle beneath the septal leaflet of the tricuspid valve. After informed consent, the patient was taken to the cardiac catheterisation laboratory for attempted occlusion.

Under general anaesthesia the femoral artery was accessed using the front loading technique.7 Repeat contrast injections in the RCA allowed visualisation of the fistula. The dilator was removed and a hand shaped 7 F sheath passed through this catheter and snared in the right ventricle (Microvena; Vadnais, Minnesota, USA). The exchange wire was exteriorised out the femoral vein forming an arteriovenous wire loop. A hand shaped 7 F sheath and dilator (Cook) were then advanced over the exchange wire from the femoral vein and positioned within the right ventricular mouth of the fistula. The dilator was removed and a 12 mm Rashkind umbrella (USCI Angiographics; CR Bard, Bellerica, Massachusetts, USA) was advanced through the sheath using the front loading technique.7 Repeat contrast injections in the RCA allowed visualisation of the device with the distal arms opened in the fistula, away from the distal coronary branches. After deployment, the device remained in a stable position and further RCA angiography showed complete closure of the defect as well as improved filling of the distal coronary branches (fig 1). Echocardiography performed during catheterisation after coil embolisation revealed trivial tricuspid regurgitation and no evidence of tricuspid stenosis. The child was observed overnight having no arrhythmias and discharged home the following day. A chest radiograph showed that the embolised coil was in a stable position within the right ventricle.

Case 2

A 2.5 year old girl was referred to our hospital because of a coronary artery fistula. Failing to thrive (weight 9.5 kg, below the fifth centile),
Physical examination was notable for a grade 4/6 continuous murmur heard at the left lower sternal border. Chest radiography revealed mild cardiomegaly and increased pulmonary vascularity, and an ECG showed left ventricular hypertrophy. Colour Doppler echocardiography showed a large coronary fistula arising from the proximal third of the RCA draining into the posterior aspect of the right atrium and a dilated left ventricle. After informed consent, left and right heart catheterisation were performed under general anaesthesia.

The patient was heparinised (150 IU/kg) and cefazolin given at a dosage of 40 mg/kg. Aortic pressure was 80/35 mm Hg (mean 58 mm Hg). Aortography and selective coronary angiography revealed a dilated RCA (measuring 8 mm proximally) and a long, tortuous coronary fistula arising from the initial third of the RCA, proximal to the origin of the first prevascular coronary branches. The fistula had a posterior course (fig 2) with two aneurysmal dilations emptying into the right atrium with two narrow exit sites. The proximal curved portion of the fistula measured 6 mm, the first pouch 17 mm and the second 11 mm. A 5 F right coronary artery catheter (Cook) was advanced into the RCA with a preload coaxial system consisting of a 0.014 inch coronary guide wire (Wizdom; Cordis) passed through a 3 F coaxial injectable catheter (Baylis Medical Company Inc, Montreal, Canada). The coronary wire was manoeuvred through the fistula and the system was snared in the right atrium using a gooseneck snare catheter (Microvena). The retrograde right coronary catheter was exteriorised out the femoral vein. The wire and the coaxial catheter were then replaced with an exchange (260 cm) 0.035 inch wire (Cook). From the femoral vein and over this wire, a hand shaped 6 F long sheath was advanced to the ascending aorta using a 6 F Gensini catheter (USCI Angiographics) as a dilator. Repeat angiography through this catheter further delineated the complete anatomy of the fistula.

The wire and the Gensini catheter were removed and an Amplatzer duct occluder (10–8 mm; AGA Medical Corp, Golden Valley, USA) was deployed. An aortogram showed complete closure of the fistula (fig 2B).

Figure 1 (A) Lateral projection of a selective injection into the right coronary artery fistula draining into the right ventricle near the tricuspid valve (case 1). (B) Same projection, after double umbrella placement, a distal injection into the right coronary artery defines improved flow to distal coronary artery branches and complete fistula closure. Note embolised coil in the right ventricle.

Figure 2 (A) Lateral projection of a selective coronary injection into the right coronary artery of case 2 defining a large, tortuous fistula draining into the right atrium. (B) After device implantation, an aortogram defines complete fistula occlusion.
Pedra, Pikhala, Nykanen, et al

Minnesota, USA) was loaded and passed through the sheath. The whole system was positioned at the proximal third of the fistula close to origin of the RCA and the device delivered according to previous published techniques.3–6 Retrograde selective right coronary injections helped to position the device. No ECG changes were noted and after 10 minutes the device was released. Repeat angiography showed complete closure of the fistula with no flow compromise to the RCA (fig 2). The following day transthoracic colour Doppler echocardiography showed that the device was well positioned within the fistula with no residual flow. The patient was discharged home on low dose aspirin.

Discussion
Many authors have described transcatheter closure of congenital coronary fistulae using a variety of techniques and devices.3–6 Nevertheless, there are few reports addressing the use of the Rashkind double umbrella or the Amplatzer septal occluder for this purpose.4, 5 The choice of device and technique is based on many factors including cost, familiarity of the operator with the different approaches, and most importantly on the anatomic characteristics of the fistula.1

In our case 1, the fistula was relatively narrow, straight, and short with important coronary branches arising close to the fistula’s right ventricle ostium. These features led to a failed coil implantation as the location of the coronary branches required the coil to be released distally and the fistula was not long enough to accommodate the coil in position. Although the Rashkind double umbrella has not been used frequently to close congenital coronary fistulae, the anatomical pattern described in this case was particularly suitable for umbrella placement.6

From a practical standpoint, certain technical requirements for umbrella implantation in the fistula are worth mentioning. Pre-shaping of the sheath (using a heat gun) along the curvature from right atrium to right ventricle and fistula was important to prevent sheath kinking, and front loading of the device allowed a smooth progression of the implant to the proper location, without the use of the rigid delivery catheter pod.7 This technique also allowed the use of a low profile sheath, facilitating entry into the narrow fistula without damaging or distorting adjacent vessels or myocardium. Optimal positioning of the device could also be monitored using retrograde repeat selective coronary injections.

The Amplatzer duct occluder is a new self-expandable device made from a Nitinol wire mesh that was originally designed to occlude persistently patent arterial ducts with initially encouraging results both in animals and humans.8–10 This device has some important advantages including a small introducer sheath (6 F) allowing its application in small children as in our case 2; the ability to recapture or reposition if misplaced, and finally a high rate of closure. The practical technical requirements described above for the front loading double umbrella technique can also be extended to the Amplatzer implantation.

A previous case in the literature showing the application of this device to close a large coronary fistula from the circumflex artery to the right atrium was similar, although the patient was older.8

Owing to various coronary fistula morphologies, the interventionist must apply specialised techniques in a creative way.9 Umbrella implantation is a useful technique to close short and non-tortuous fistulae that drain into the right ventricle and are located near significant coronary branches. Similarly, implantation of the Amplatzer duct occluder appears to be particularly useful to close large, high flow fistulae that drain into the right ventricle or right atrium in the small children.
