Partial left ventriculectomy improves left ventricular end systolic elastance in patients with idiopathic dilated cardiomyopathy

Z Popović, M Mirić, S Gradinac, A N Nešković, M Bojić, A D Popović

Abstract
Objective—To assess the effect of partial left ventriculectomy (PLV) on estimate of left ventricular end systolic elastance (Ees), arterial elastance, and ventriculoarterial coupling.
Patients—11 patients with idiopathic dilated cardiomyopathy before and after PLV, and 11 controls.
Interventions—Single plane left ventricular angiography with simultaneous measurements of femoral artery pressure was performed during right heart pacing before and after load reduction.
Results—PLV increased mean (SD) Ees from 0.52 (0.27) to 1.47 (0.62) mm Hg/ml (p = 0.0004). The increase in Ees remained significant after correction for the change in left ventricular mass (p = 0.004) and end diastolic volume (p = 0.048). As PLV had no effect on arterial elastance, ventriculoarterial coupling improved from 3.25 (2.17) to 1.01 (0.93) (p = 0.017), thereby maximising left ventricular stroke work.
Conclusion—It appears that PLV improves both Ees and ventriculoarterial coupling, thus increasing left ventricular work efficiency.

Keywords: dilated cardiomyopathy, elastance, partial left ventriculectomy

Previous studies have shown that partial left ventriculectomy (PLV), a surgical procedure originally described by Batista, leads to a significant reduction in left ventricular volume while simultaneously increasing ejection fraction. Mathematical modelling also predicts that volume reduction by PLV increases left ventricular end systolic elastance— that is, the steepness of end systolic pressure–volume relations. However, clinical data on the effects of PLV on this load independent measure of left ventricular contractility are controversial.

We report the effects of PLV on left ventricular end systolic elastance in patients with severely symptomatic idiopathic dilated cardiomyopathy.

Methods
PATIENTS
We assessed 11 male patients that represented a subgroup of 19 previously reported patients who underwent successful PLV with technically satisfactory data for estimating pre- and postoperative left ventricular end systolic elastance. In eight patients end systolic elastance data could not be calculated because of technical reasons and they were not included in this analysis. (In seven patients only one adequate preoperative ventricular angiogram was obtained because of the following: four patients had extrasystoles, in two patients surgery was performed using a previously described modification. The procedure involved a diamond shaped resection of the left ventricular posterolateral wall confined by two papillary muscles. The resected myocardial specimen was 9.1 (2.5) cm long, 4.5 (1.3) cm wide, and...
improvement of Ees (p = 0.0004) (A). Improvement of Ees by PLV persisted after multiplying Ees with left ventricular mass (Ees*LV mass) (p = 0.0004) (B), and after multiplying Ees with left ventricular end diastolic volume (Ees*LV EDV) (p = 0.0048) (C).
The end systolic pressure was then replaced with peak systolic pressure and the method repeated, with a resulting regression slope considered as a second end systolic elastance estimate (Ees). Previous studies have shown a good correlation between these two estimates and more accurate measures of left ventricular end systolic elastance. To eliminate the impact of change of left ventricular size on end systolic elastance, we calculated corrected Ees by dividing arterial elastance by Ees. To clarify the impact of surgical correction of mitral regurgitation on Ees, we assessed correlation between interobserver variability of measurements of the same variables were \( r = 0.95, 0.96, \) and 0.72, respectively. The mean (SD) of absolute differences of intraobserver measurements of left ventricular end diastolic and end systolic volumes and for the end systolic volume decrease after the glyceryl trinitrate bolus were 19.0 (14.1) ml, 10.5 (11.0) ml, and 11.8 (10.1) ml, respectively; the mean of absolute differences of interobserver measurements of the same variables were 23.6 (20.7) ml, 17.3 (13.6) ml, and 11.1 (7.4) ml, respectively.

End systolic pressure was defined as the dicrotic notch of the femoral artery pressure tracing recorded during left ventricular angiography. Left ventricular end diastolic wall thickness was measured as the distance between epicardial and endocardial surfaces of the anterior free wall in its middle third, and the result was used for determination of ventricular mass.

Left ventricular end systolic elastance was estimated by two methods. First, the matched points of end systolic pressure–volume relation were subjected to a linear regression. The regression slope was considered to be the first end systolic elastance estimate (Ees), while its intercept with the abscissa was considered to be the theoretical volume at zero pressure. The impact of change of left ventricular size on end systolic elastance was considered as a second end systolic elastance estimate (Eps). Previous studies have shown a good correlation between these two estimates and more accurate measures of left ventricular end systolic elastance. To eliminate the impact of change of left ventricular size on end systolic elastance, we calculated corrected Ees by multiplying it with either left ventricular mass or end diastolic volume. Arterial elastance was calculated as the ratio of end systolic pressure to stroke volume, and ventriculoarterial coupling was calculated by dividing arterial elastance with Ees.

**Statistics**

All data are presented as mean (SD). Paired t tests were used to compare patients’ data before and after surgery and unpaired t tests were used for comparisons between controls and patients, using Bonferroni’s correction for multiple comparisons. Simple linear regression was used to assess correlation between variables. The impact of correction of mitral regurgitation on Ees was assessed by repeated measures analysis of variance. A value of \( p \leq 0.05 \) was considered significant.

**Results**

Following PLV, left ventricular mass index significantly decreased from 163 (24) to 141 (27) g/m², \( p = 0.001 \); this corresponded to a relative decrease of left ventricular mass of 14.4 (7.0)%. This was associated with a decrease of end diastolic volume from 129 (36) to 50 (24) ml/m², \( p < 0.0001 \) and of end systolic volume from 129 (36) to 50 (24) ml/m², \( p < 0.0001 \). We also found a significant increase in ejection fraction from 25 (7) to 42 (10)%, \( p = 0.0006 \). An improvement of Ees after PLV was detected in all patients, from 0.52 (0.27) to 1.47 (0.62) mm Hg/ml \( p = 0.0004 \) (fig 1). Similar improvements were obtained for Eps, from 0.58 (0.36) to 1.73 (0.88) mm Hg/ml \( p = 0.002 \) (table 1). There was a good overall correlation between Ees and Eps \( r = 0.95, p < 0.0001 \). In addition, there was a significant linear correlation between the logarithm of Ees and the ejection fraction \( r = 0.77, p < 0.0001 \). The increase of Ees remained significant after correction for the change of left ventricular mass, from 163 (91) to 420 (238) mm Hg/ml \( p = 0.004 \), as well as after correction for the change of end diastolic volume from 165 (77) to 281 (141) mm Hg \( p = 0.048 \). There was no change in theoretical volume at zero pressure (11.3 (102.5) v 37.6 (49.5) ml, \( p > 0.05 \)), and in arterial elastance \( (1.36 (0.46) v 1.18 (0.50) \) mm Hg/ml, \( p > 0.05 \) after surgery. Finally, an improvement in ventriculoarterial coupling (from 3.25 (2.17) to 1.01 (0.93), \( p = 0.017 \) occurred after surgery.

To clarify the impact of surgical correction of mitral regurgitation on Ees change after PLV,
we divided patients into two groups: a group with no or mild preoperative mitral regurgitation (grade < 2 by ventricular angiography, n = 6), and a group with severe mitral regurgitation (grade > 2, n = 5) (fig 2). Compared to patients with no or mild mitral regurgitation, patients with severe mitral regurgitation had lower values of Ees both before (0.29 (0.22) v 0.70 (0.09) mm Hg/ml) and after PLV (1.14 (0.53) v 1.74 (0.60) mm Hg/ml) (p = 0.02). However, the amount of postoperative increase in Ees in both groups was similar (p > 0.05).

**Discussion**

Published data on the effects of PLV on left ventricular end systolic elastance are controversial. While Bellotti and colleagues found a postoperative increase of end systolic elastance (using M mode echocardiography coupled with simultaneous measurement of left ventricular pressures), Gorcsan and colleagues reported variable intraoperative effects of PLV on end systolic elastance. The results of Gorcsan and colleagues may have been influenced by immediate postoperative left ventricular depression, as well as by a small number of patients with both pre- and postoperative data.

In contrast, we have found a significant improvement in end systolic elastance. End systolic elastance reflects the ability of the left ventricle to resist distending forces generated by an increase of systolic pressure. This measure of left ventricular contractility gains importance in a setting of decreased end diastolic volume after PLV. Two recent papers predicted an increase of end systolic elastance following ventricular volume reduction by using different methods of mathematical modelling. Thus, a decrease of end systolic elastance postoperatively would imply deleterious effects of PLV procedure on left ventricular function. Therefore, a similar or decreased postoperative end systolic elastance would seriously challenge proposed beneficial effects of PLV. In our study, all patients had a significant increase of two Ees. Interestingly, the magnitude of this increase was greater than anticipated and it was still significant after correction for changes of left ventricular mass and end diastolic volume. This may suggest that postoperative change of Ees is not related to the change of left ventricular size only, but to the change of its shape as well.

Our data indicate that PLV improves Ees. In addition, this increase improves postoperative ventriculoarterial coupling, suggesting better left ventricular pump efficiency, which may be responsible for the beneficial haemodynamic effects of PLV.
