Depression, stress, and the heart

P C Strike, A Steptoe

Evidence is accumulating that psychosocial factors, in particular depression, contribute to coronary artery disease

There is rapidly growing interest in the interactions between heart and mind. Evidence is accumulating from epidemiological and clinical studies that psychosocial factors contribute to coronary artery disease (CAD). Depression is a common problem with a high degree of associated disability, and has been the focus of much of this work. Depressed individuals are more likely to develop angina, or fatal or non-fatal myocardial infarction, than their non-depressed counterparts. A review of the prospective epidemiological cohort studies into depression and the subsequent development of CAD has shown a possible aetiologic role for depression or hopelessness in eight out of eight studies, even after adjustment for traditional cardiovascular risk factors.1 Overall these studies show a relative risk of approximately twofold of developing CAD for depressed compared with non-depressed groups, with some studies showing a dose–response effect in which greater exposure to depression leads to a higher incidence of coronary events.2 For example, a four year follow up of the Amsterdam longitudinal ageing study reported a relative risk of cardiac mortality of 1.6 for individuals with depressive symptoms, and 3.8 for those with clinically diagnosed depression, after adjustment for age, sex, education, smoking, alcohol, hypertension, body mass index, diabetes, stroke, and cancer.3 The John Hopkins precursors study4 followed 1190 medical students for a median of 37 years, and found a median interval of 15 years between the first episode of depression and the first coronary event. This suggests a chronic underlying link, with depression pre-dating the development of clinical CAD. Duration of symptoms themselves may also influence the risk of mortality.5 More recently, it has been found in the Whitehall II study that British civil servants with elevated scores on the general health questionnaire (an inventory screening for psychological distress in the general population) were at increased risk of developing coronary heart disease over a five year period, independently of other psychosocial factors including socioeconomic status.6

DEPRESSION FOLLOWING MYOCARDIAL INFARCTION

Depression is an adverse prognostic factor in patients with a diagnosis of CAD.1 Between 15–20% of patients experience major depressive illness after myocardial infarction, and many more experience depressive symptoms. There is a threefold greater incidence of depression in CAD patients compared with the general public.1 The majority of studies suggest an association with poor prognosis,6 although this has not been a uniform finding.7 Recently, a link between level of depressive symptoms assessed soon after myocardial infarction and five year survival has been demonstrated.8 These findings have prompted a search for the psychobiological mechanisms linking CAD and depression.

IMMUNOLOGICAL ABNORMALITIES

Depression is associated with abnormalities of platelet function, blood coagulation, immune function, the hypothalamic–pituitary–adrenocortical axis, autonomic balance, folate/homocysteine metabolism, and endothelial function, all of which may play a role in the atherosclerotic disease process. With the growing evidence for atherosclerosis as an inflammatory process, there has been much interest in inflammation as a mediator between depression and CAD. Depression is associated with an acute phase response as evidenced by a higher C reactive protein and raised concentrations of pro-inflammatory cytokines such as interleukin-6 (IL-6). Interleukin-1β (IL-1β), tumour necrosis factor α (TNFα) as well as interleukin-1 receptor antagonist (IL-1Ra) are also raised in depressed patients.9 These pro-inflammatory cytokines can produce symptoms of depression, anorexia, weight loss, malaise, anhedonia, and sleep disturbances.9 10 Raised concentrations of intercellular adhesion molecule-1 (ICAM-1), E-selectin, and monocyte chemo-attractant protein-1 (MCP-1) are present in depressed individuals as well,11 and may play a role in the cellular infiltration associated with atherosclerotic disease.

HAEMATOLOGICAL ABNORMALITIES

Depressed persons also have haematological abnormalities leading to a prothrombotic state. There is a higher white blood cell count, fibrinogen, and factor VIIc in depressed than non-depressed people.12 Concentrations of platelet factor IV and β thromboglobulin are also raised.13 The raised IL-6 in depression is positively correlated with the number of leucocytes, neutrophils, and CD2+ T and CD4+ T cells.14 Platelet activation may contribute to the link between depression, thrombus formation, and haemostasis. Platelet activation is greater in depressed than
non-depressed patients with CAD, with increased activation of glycoprotein IIb/IIIa receptors. Depressed patients without CAD also have significantly increased 5-hydroxytryptamine (5HT) mediated platelet activity compared with non-depressed controls, possibly caused by upregulation of platelet 5HT_x receptors.

The association between depression and CAD may be explained in several possible ways: depression could lead to inflammation which in turn leads to CAD; an inflammatory process could cause both central nervous system disturbances (and depression) and CAD; both could be a product of atherosclerotic vascular disease; both could arise from chronic strain in the social environment; or depression could lead to CAD via the adoption of health compromising behaviours such as smoking, poor diet, lack of exercise, and poor adherence to treatment.

VASCULAR ENDOTHELIAL DYSFUNCTION

The study by Broadley and colleagues in this issue of Heart points to another pathophysiological process relating depression to cardiovascular risk, namely vascular endothelial dysfunction. Endothelium dependent flow mediated dilatation (FMD) was assessed in the brachial arteries of patients with proven depression currently taking antidepressant therapy, and compared with that of non-depressed controls. The depressed patients showed impaired FMD. Patients had been treated for a minimum of three months, were considered to be in remission at the time of study, and none had pronounced cardiovascular risk factors. These results are complimentary to the work described by Rajagopalan and colleagues, who demonstrated a pronounced attenuation of FMD in young depressed patients without conventional cardiovascular risk factors. These results are complimentary to the work described by Rajagopalan and colleagues, who demonstrated a pronounced attenuation of FMD in young depressed patients without conventional cardiovascular risk factors. These results are complimentary to the work described by Rajagopalan and colleagues, who demonstrated a pronounced attenuation of FMD in young depressed patients without conventional cardiovascular risk factors. These results are complimentary to the work described by Rajagopalan and colleagues, who demonstrated a pronounced attenuation of FMD in young depressed patients without conventional cardiovascular risk factors.

Rajagopalan and colleagues found a 3.8% increase in brachial artery diameter in their depressed patients compared with a 9.6% increase in the control group. The percentage changes in FMD seen in Broadley's study were –0.7% in the depressed patients versus 5.7% in the control group. The glyceryl trinitrate induced endothelium independent dilatation was very similar in the two studies and was similar to controls. The patients in Broadley's study were 10 years older on average than those in Rajagopalan's study, and this, or indeed the presence of antidepressant medication, may have contributed to the difference in absolute FMD response. No information is given regarding duration of depressive symptoms. Endothelial function is significantly affected by cardiovascular risk factors such as smoking, hypertension, and lack of physical fitness. All are typically more prevalent in depressed persons in the community, which may mean that the degree of endothelial impairment seen in these studies is an underestimate of the true effects.

Brief episodes of acute mental stress have been shown to cause endothelial dysfunction for up to 1.5 hours in healthy individuals. Nitric oxide production has an antiatherogenic effect by inhibiting cellular adhesion, migration, and proliferative responses, so stress related endothelial impairment may affect the integrity of the vascular endothelium. If stress responses are chronic or repeatedly elicited during everyday life, the result may be acceleration of atherosclerosis. One model of depression is that it mirrors a low-grade chronic emotional stress reaction. This might lead to subclinical disturbances of the endothelial, haematological, immune, and neuroendocrine function, allowing the initiation and subsequent progression of atherosclerotic lesions. The psychosocial factors, apart from depression, that have been most consistently associated in prospective studies with CAD are low socioeconomic status, work-related stress, and social isolation. These factors may cluster with depressive symptoms, further exacerbating risk.

ANTIDEPRESSANT TREATMENT

Depression can be successfully symptomatically treated in depressed patients with CAD. However, there has been concern that some medications such as tricyclic antidepressants have a cardiotoxic effect on rate and rhythm. There is also evidence that selective serotonin reuptake inhibitors, especially paroxetine, have in vitro and in vivo inhibitory effects on nitric oxide synthase, and this may translate into a deleterious effect on endothelial function. This clearly has implications for its use in patients with CAD, although more evidence is needed to change current practice. Pharmacological treatment is unlikely to be appropriate for all patients with CAD, since cardiac risk is apparently increased at subclinical levels of depressive symptoms for which drug treatment is not warranted. However, initial reports from recent trials of cognitive behaviour therapy (ENRICHD—enhancing recovery in coronary heart disease patients) and sertraline (SADHART—sertraline antidepressant heart attack randomised trial) for depressed patients following myocardial infarction have also yielded disappointing results.

It is interesting that Broadley and colleagues observed impaired endothelial function, even though depression had been effectively treated. Other groups have also found that treating depression does not reverse all of the accompanying pathophysiological abnormalities. Maes and associates found that antidepressant treatment did not significantly reduce the raised serum IL-6 or IL-1Ra concentrations in depressed patients, although the elevation in IL-6 was more pronounced in the patients with treatment resistant depression. Similarly, effective treatment is not associated with normalisation of the abnormalities of heart rate variability or baroreflex sensitivity seen in depression. It is probable that treatment for depression will not reduce mortality and morbidity from CAD unless it tackles the underlying link between depression and CAD, rather than just the symptoms of depression. Medication affecting the symptoms alone may have limited benefits which need to be balanced against deleterious effects. It may be that some depression in cardiac patients is a manifestation of an underlying inflammatory process, and that treating the symptoms does not necessarily treat the crucial elements of the disease.

Ventricular tachycardia as a presenting feature of dermatomyositis

A 47 year old man suffered recurrent episodes of exertional syncope for three months, and hospital admission was precipitated by syncope while driving. A telemetry recording showed episodes of ventricular tachycardia during minimal exertion (below left). He was noted to have Gottron’s sign (fuscia coloured, elevated, slightly scaly patches over the knuckles indicating dermatomyositis) (right, upper panel) and “car mechanic’s” hands (fissuring of the paraungual areas seen in dermatomyositis and overlap connective tissue disease) (lower panel), and reported proximal muscle pain. Further investigation revealed normal coronary arteries, and a persistently elevated troponin I concentration, consistent with the clinical diagnosis of dermatomyositis complicated by cardiac muscle involvement. Computed tomographic scan of the thorax confirmed the presence of pulmonary fibrosis as a feature of his connective tissue disease.

Treatment with sotalol 40 mg three times daily, prednisolone 40 mg once a day, and azathioprine 150 mg once a day led to resolution of symptoms and a decrease in troponin I concentrations to the normal range. After 18 months of follow up the patient remains well and free of syncope. This case illustrates the importance of cardiac muscle involvement in dermatomyositis. Troponin I but not creatine kinase MB, which is overexpressed by regenerating skeletal muscle and usually elevated in dermatomyositis, might be useful to monitor cardiac muscle involvement in this disease.
