**Ischaemic heart disease**

Inflammation marks the risk  
CD40 ligand is released from activated lymphocytes and platelets, and is proinflammatory. The concentrations of soluble CD40 ligand were raised (above 5.0 µg/l) in 221 of 626 patients with acute coronary syndromes (40.6%). Raised soluble CD40 ligand values identified those with acute coronary syndromes who were at high risk for death or non-fatal myocardial infarction (MI) (hazard ratio v with those with low levels, 6.65, 95% confidence interval (CI) 3.18 to 13.89; p < 0.001) independent of troponin concentrations. Elevation of soluble CD40 ligand identifies a subgroup of patients at high risk who are likely to benefit from antiplatelet treatment with abciximab (adjusted hazard ratio as compared with those receiving placebo, 0.37, 95% CI 0.20 to 0.68; p = 0.001). Whether this adds to assessment using C reactive protein, a better validated risk marker, was not tested.

**Inform consent for acute MI trials is nearly impossible**  
Patients being asked to take part in a trial with approved protocol were assessed to see what information they were able to take in during the stress of an acute MI. The patient information sheet needed education to age 18 for comprehension, although only 75 of 345 patients (22%) had been educated beyond secondary school. Only 63 of 346 (18%) read the patient information sheet before giving or refusing consent to participate. Patients who gave consent were more likely to report good or partial comprehension of the information provided than were those who refused consent. In an assessment of competence to make a decision, 75 of 145 (52%) were ranked at the lowest grade and 26 (18%) were not competent to consent.

**No role for antibiotic treatment in ACS**  
In the AZACS trial of 1439 patients with unstable angina or acute myocardial infarction, patients were randomly allocated to receive 500 mg azithromycin on the first day after randomisation, followed by 250 mg daily for four days or placebo. Treatment with azithromycin did not result in reduction of any of the primary end points of death, MI or revascularisation. This is in line with two previous trials (ACADEMIC and ROXIS), but disagrees with earlier smaller studies.

**General cardiology**

Three minutes of CPR pre-shock in out-of-hospital VF arrests may improve outcomes  
In a randomised trial of 200 patients presenting with out-of-hospital ventricular fibrillation (VF) to casualty, there was no difference between standard group (DC shock first) versus patients receiving three minutes of cardiopulmonary resuscitation (CPR) and then DC cardioversion. However, for patients with response intervals [arrest to arrival of ambulance] of longer than five minutes, more patients achieved an output in the CPR first group compared with the standard group (58% v 38%; odds ratio (OR) 2.22, 95% CI 1.06 to 4.63; p = 0.04); survival to hospital discharge (22% v 4%; OR 7.42, 95% CI 1.61 to 34.3; p = 0.006); and one year survival (20% v 4%; OR 6.76, 95% CI 1.42 to 31.4; p = 0.01). Thirty three (89%) of 37 patients who survived to hospital discharge had no or minor reductions in neurological status with no difference between the groups.

Troponin may have a role in assessing CV risk in renal failure patients  
The annual mortality in haemodialysis patients is 23%, mainly from cardiovascular events. A total of 137 patients on chronic dialysis were enrolled for baseline troponin I (raised > 1 ng/ml) and followed for 15 months. Patients with a history of acute coronary syndrome (within 30 days) were excluded. Of the 137, 10 patients (7%) had a raised troponin I value at baseline. At 15 months, four of the 10 patients had died compared with 12% of those with normal values (hazard ratio 9.6, 95% CI 2.8 to 33; p < 0.01). This persisted after multivariate analysis. The reason for the rise was not clear.

ICDs save lives  
Eight trials were included in the analysis (4909 patients, 1154 deaths). Compared with usual care (most commonly amiodarone treatment), regardless of baseline risk, implantable cardioverter-defibrillators (ICDs) were equally efficacious in preventing sudden cardiac death in both secondary prevention (relative risk (RR) 0.50, 95% CI 0.38 to 0.66) and primary prevention in higher risk groups (RR 0.37, 95% CI 0.27 to 0.50).

Results of MADIT-2 suggest any previous acute MI puts you in the latter category. As for statins, who you treat depends on what you can afford as a health service.
A 33-year-old man had Wilson's disease. One month after a successful second liver transplant he developed a fever. He was being treated with steroids and immunosuppressive drugs. A subclavian central line had been removed two weeks previously. Multiple blood cultures grew methicillin-sensitive Staphylococcus aureus. Vancomycin and gentamicin treatment was started. Transoesophageal echocardiography showed a large mobile mass (22 × 13 mm diameter) attached to the atrial surface of the anterior leaflet of the tricuspid valve (left hand panel). Open heart surgery was performed. The elongated friable vegetation, attached to the tricuspid valve (right hand panel), was excised. The valve defect was repaired with a pericardial patch. Pathological examination of the vegetation showed extensive infiltration with S aureus. The patient made an uneventful recovery. Follow up echocardiography demonstrated normal valve motion and minimal tricuspid regurgitation.
