B Type natriuretic peptide: a good omen in myocardial ischaemia?

S P D’Souza, G F Baxter

Although BNP is now firmly established as a diagnostic and prognostic marker of ventricular dysfunction, its autocrine and paracrine actions within the heart have received less attention.

The natriuretic peptide family consists of a number of structurally homologous but genetically distinct polypeptide mediators. The peptides are highly conserved across mammalian and invertebrate species and, in humans, are released from various tissues in response to physiological and pathological stimuli. All the peptides have at their core a 17-amino acid disulfide ring essential for receptor recognition and biological function.

The first description of secretory granules in the cardiac atria was given in 1956, to be followed by the physiological characterisation of an atrial natriuretic factor in the work of de Bold and colleagues in 1981. Several further natriuretic peptides have subsequently been identified. These include B type natriuretic peptide (BNP) predominantly from ventricular myocardium (although originally isolated from pig brain) and C type natriuretic peptide (CNP) expressed in the nervous system and endothelial cells. A homologue of the natriuretic factor, DNP, in the venom of the green mamba Dendroaspis angusticeps, is found in plasma and atrial myocardium of normal humans. Urodilatin is a renal derived natriuretic peptide, ANP and BNP are the predomi-

niant natriuretic peptides in mammalian cardio-

myocytes, are stored within secretory granules as pro-peptides, pro-ANP and pro-BNP, that are post-translationally modified by peptide bond cleavage to form the mature circulating peptides and amino (N)-terminal residues.

Biological activity of the peptides generally resides in the mature carboxy-terminal residues, although pro-ANP and pro-BNP may exhibit some activity. The (N)-terminal residues are generally inactive. Relatively little is known about the processing of BNP in the circulation. The peptides are eventually cleared by the natriuretic peptide-C receptor (NPR-C)—a clearance receptor. Binding of natriuretic peptides to NPR-C leads to internalisation and degradation.

Neutral endopeptidase 24.11 (NEP) also takes part in the inactiva-
tion of natriuretic peptides and there is a minor contribution from renal excretion. Both NPR-C and NEP are widely expressed in the kidneys, lungs, and the vascular wall.

A variety of physiological and pathological stimuli evoke the release of ANP and BNP. Such stimuli include exercise, hypoxia, ischaemia, increased wall stress and dilatation of the cardiac chambers, and sepsis. The classical endocrine actions of ANP and BNP, namely vasodilatation and natriuresis, are mediated by interaction with a natriuretic peptide receptor (NPR)-A which is a partuculate guanylyl cyclase (pGC). This cyclase subserves the same biochemical function as soluble guanylyl cyclase (sGC)—the principal intra-
cellular receptor for NO—namely, the conversion of guanosine triphosphate to cyclic guanosine monophosphate (cGMP). NPR-A is widely ex-
pressed in cardiovascular tissues, and its activa-
tion by ANP and BNP leads to elevation of intra-
cellular cGMP and activation of the cGMP de-
pendent protein kinase (PKG-I). CNP engages
another receptor subtype, NPR-B, also a pGC receptor, while DNP acts via NPR-A, mediating a predominant vasorelaxing action.

BNP RELEASE IN CARDIAC DYSFUNCTION AND MYOCARDIAL ISCHAEMIA

BNP is released following left ventricular over-
loading and wall stress, underpinning its diag-
nostic and prognostic value in patients with heart failure. Other cardiac pathologies including hypertensive heart disease, atrial fibrillation, and valvar heart disease are also associated with elevation of circulating BNP. Experimental and clinical myocardial infarction is clearly associated with gradual and sustained elevation of tissue and circulating BNP. BNP is deemed to be a strong independent predictor of prognosis in patients with heart failure and following myocardial infarction.

However, the rapid release of BNP following very brief periods of ischaemia, insuffi-
cient to provoke irreversible tissue injury or pronounced changes in end diastolic volume, is of considerable interest. Elevated concentrations of BNP in humans are detected following unstable angina and immediately after short balloon inflations during coronary angioplasty. In the rat heart, experimental ischaemia of as little as two minutes leads to an immediate increase of BNP outflow, which correlates with the duration of ischaemia.

Such observations are a stimulus to identifying the functional role of BNP in the ischaemic myocardium.

Abbreviations: ANP, atrial natriuretic peptide; BNP, B type or brain natriuretic peptide; CNP, C type natriuretic peptide; DNP, Dendroaspis natriuretic peptide; K_ATP, ATP dependent potassium channel; NEP 24.11, neutral endopeptidase; NO, nitric oxide; NPR, natriuretic peptide receptor; pGC, particulate guanylyl cyclase; PKG-I, cGMP-dependent protein kinase subtype I; sGC, soluble guanylyl cyclase.

BNP MODIFIES ACUTE ISCHAEMIC INJURY

Myocardial ischaemia triggers the release of a number of endogenous cytoprotective mediators. These include adenosine, opioid peptides, and bradykinin. However, the role of BNP in modifying acute myocardial ischaemic injury has only recently been identified. In a rat heart model of acute myocardial infarction, exogenously administered BNP limited infarct size in a concentration dependent manner. This action was independent of the peptide’s endocrine actions that lead to systemic haemodynamic unloading, or to recruitment of native coronary collateral vessels, pointing to a primary cytoprotective action.

The mechanism of this acute protective effect of BNP appears to be associated with an increase of the second messenger cGMP and involves opening of ATP sensitive potassium (KATP) channels (fig 1). Pharmacological evidence suggests that this channel may be a mitochondrial KATP channel, rather than the sarcolemmal KATP channel. There is further evidence that the nitric oxide/soluble guanylyl cyclase (NO/sGC) system may also play a role in the anti-ischaemic actions of BNP that we have described. There is recent evidence for a “cross-talk” between the BNP/NPR-A pathway and the NO/sGC pathway in vascular cells and this may also be relevant to the myocardium.

The mitochondrial KATP channel has been prominent recently in relation to protection of the ischaemic myocardium by preconditioning and other protective strategies. Many endogenous protective mediators are thought to produce their anti-ischaemic actions through mitochondrial KATP channel opening, so why should BNP be regarded differently from, say, adenosine or bradykinin? One reason is the novel molecular signalling pathway employed by BNP. We postulate that BNP/NPR-A induced elevation of cGMP with activation of cGMP-dependent protein kinase-I (cGK-I or protein kinase-G-I) is a plausible mechanism of KATP channel opening via the cGMP/cGK-I pathway, and may therefore represent an alternative signalling cascade resulting in tissue protection and salvage. Most of the endogenous mediators of cardioprotection studied so far act on G-protein-coupled receptors. In several disease states, including cardiac hypertrophy and cardiac failure, there may be downregulation of G-protein-coupled receptor responses. Under these conditions, the BNP/NPR-A signalling pathway could act as a very effective reserve salvage pathway.

BNP MAY INFLUENCE POSTINFARCTION REMODELLING

The sustained elevation of cardiac BNP expression following myocardial infarction is likely to be a reflection of important counter-regulatory actions of natriuretic peptides on cell growth and proliferation. These actions may include inhibition of fibroblast activity and an antihypertrophic effect on cardiac myocytes. Following infarction, ANP and BNP exert potent actions on cardiac fibroblasts. Both peptides inhibit collagen synthesis by cardiac fibroblasts in response to hypoxia in vitro and they inhibit fibroblast proliferation in response to angiotensin II stimulation. Recently, multifocal cardiac fibrosis has been described in mice with deletion of the bnp gene. NPR-A knockout mice also develop hypertension with an exaggerated cardiac hypertrophy and fibrosis. Limited information is available on the role of natriuretic peptides in regulating cardiomyocyte growth. In cultured cardiac myocytes, natriuretic peptides inhibit hypertrophy and in vascular smooth muscle cells, BNP and CNP inhibit growth and proliferation. The mechanism of growth inhibition is far from clear but may involve an inhibitory action on the mitogen activated protein kinase cascade. Another action of natriuretic peptides that may be relevant to tissue remodelling is the ability to stimulate apoptosis. However, this issue is presently unresolved. Although cyclic nucleotides such as cGMP, the principal second messenger in the BNP/NPR-A signalling pathway, are known to regulate the processes of cell proliferation, differentiation, and apoptosis, there are currently no clear patterns to predict how cGMP could modify apoptosis in ischaemic myocardium.

Figure 1 Mechanism of acute protective effect and growth modifying actions of BNP.
CONCLUSION
In conclusion, BNP is now firmly established as a diagnostic and prognostic marker of ventricular dysfunction, but its autocrine and paracrine actions within the heart have received less attention. Experimental evidence suggests that BNP is a pleiotropic peptide and its salutary effects in acute ischaemia and following infarction go beyond its classic natriuretic and cardiac unloading effects. Therapeutically, this range of actions could be of great benefit. Conceivably, the therapeutic cardiac unloading effects. Therapeutically, this range of pleiotropic peptide and its salutary effects in acute ischaemia and prognostic marker of ventricular dysfunction, but its
