ABSTRACT
Objective Plasma cancer antigen (CA)-125 is a tumour marker recently shown to be associated with systolic heart failure and new-onset atrial fibrillation (AF) after myocardial infarction. However, no reports have described the relationship between CA-125 and new-onset AF in healthy postmenopausal women. The aim of the present study was to evaluate the relationship between CA-125 and new-onset AF in postmenopausal women.

Methods Between 2005 and 2015, 2086 women, including 1012 postmenopausal women, visited our hospital for annual health check-ups. We excluded patients with systolic dysfunction, chronic inflammatory disease, chronic obstructive pulmonary disease, histories of AF or neoplastic diseases. A total of 746 postmenopausal women underwent thorough physical examinations, including those for biomarkers such as brain natriuretic peptide, high-sensitivity C-reactive protein (hs-CRP) and CA-125.

Results During the 10-year observation period, AF was documented in 31 participants (4.2%). The mean age of participants developing AF (75±6 years) was higher than that of those without AF (68±8 years). Participants developing AF showed significantly higher CA-125 (11.4±6.3 U/mL) and hs-CRP (0.10±0.11 mg/dL) levels than did those without AF (7.7±3.2 U/mL, p<0.01; 0.07±0.08 mg/dL, p<0.05). Cox regression analyses revealed ageing (HR 1.3; 95% CI 1.08 to 1.57; p<0.01) and plasma CA-125 levels (HR 1.29; 95% CI 1.10 to 1.51; p=0.02) as independent predictors of AF.

Conclusions High CA-125 levels might be associated with new-onset AF in healthy postmenopausal women.

INTRODUCTION
Atrial fibrillation (AF) is one of the most common arrhythmias and is a leading cause of mortality; its prevalence ranges from 0.5% to 1% in the general population.1 However, in the last decade, the AF prevalence has been commonly believed to be markedly higher, based on the number of hospitalisations, emergency room visits and outpatient visits due to AF.2 Some patients with AF have no symptoms; however, AF sometimes leads to serious complications, including cardiomyopathic stroke, heart failure (HF) and death. Paroxysmal AF may progress to permanent AF as electrical and structural remodelling of the atrium acts to perpetuate abnormal electrical rhythms.3,4,5 AF is commonly associated with ageing,6 male sex,6 obesity,7 hypertension (HTN),8 diabetes mellitus (DM),9 myocardial infarction,10 HF,10 or underlying structural heart diseases11 such as valvular heart disease or cardiomyopathy. In ageing societies, the AF prevalence is rapidly increasing; early detection and treatment of AF are, therefore, vital to the health of the patient. The use of biomarkers, such as high-sensitivity C-reactive protein (hs-CRP),12 interleukin-6 (IL-6),13 tumour necrosis factor-alpha (TNF-α),14 and serum N-terminal pro-brain type natriuretic peptide (NT-proBNP),14 has been reported to detect AF.

Nagele et al15 first reported elevated serum levels of cancer antigen-125 (CA-125) following heart transplantsations. Now, CA-125 is a well-established tumour marker related to ovarian cancer and is used to monitor the efficacy of ovarian cancer therapy. Recently, several studies have reported the relationships between CA-125 and HF with reduced ejection fraction, HF with preserved ejection fraction16 and ischaemic heart disease.17 Yucel et al18 reported that CA-125 levels are associated with the development of new-onset AF in patients hospitalised for systolic HF. However, no studies regarding the relationship between CA-125 and paroxysmal or persistent AF have been reported in healthy postmenopausal women. The present study aimed to evaluate the relationship between CA-125 and new-onset AF in this population.

METHODS
Study design
All participants were Total Health Care (THC) members at Aoyama Hospital, Tokyo Women’s Medical University, or Health Mate members at the Institute of Geriatrics, Tokyo Women’s Medical University. THC and Health Mate are health check-up systems offered by our institution to more than 3000 registered members. The participants were admitted for annual health check-ups between April 2006 and August 2015. During these check-ups, we conducted detailed health examinations that included blood tests for several tumour makers, detailed metabolic profiles, two-dimensional echocardiography, pulmonary functional tests, chest CT scans, head MRI/angiography, gastrointestinal endoscopy and abdominal ultrasonography. Registered members...
are monitored for several years; the median follow-up period is 8.0 years.

We analysed and compared several previously reported AF risk factors, including ageing, HTN, DM, and cardiac ultrasound parameters for left atrial diameter (LAD) and left ventricular ejection fraction (LVEF). We also measured several biomarkers, including hs-CRP, NT-proBNP and CA-125, using the data obtained from the records of our unique medical check-up system.

### Study protocol

**Participants and protocol**

The participants were registered THC or Health Mate members who underwent annual medical check-ups between 2006 and 2015. All participants had their histories and the results of the following physical examination parameters recorded. (1) Blood sampling was performed after 12 hours of overnight fasting (plasma triglyceride (TG), high-density lipoprotein cholesterol (HDL-C), low-density lipoprotein cholesterol (LDL-C), fasting plasma glucose (FPG), haemoglobin (Hb); serum albumin concentration (Alb); uric acid (UA); hs-CRP; and serum creatinine (Cr) were measured using standard laboratory techniques). (2) Blood pressure was measured after a 10 min rest, in sitting position, and expressed as the average of three consecutive measurements of each arm by using the conventional cuff method. (3) All participants underwent echocardiography. (4) Pulmonary functional tests were performed with the following parameters: the ratio of forced expiratory volume in 1 s (FEV1) and forced vital capacity (VC, expressed as the per cent of the predicted value for the individual’s age and sex). The annual health check-up items are listed in online Supplementary table 1.

The inclusion criteria were women older than 45 years having more than 12 months of amenorrhoea on first examination at our hospitals. The exclusion criteria included the following: (1) history or findings of cardiovascular disease, including HF symptoms or systolic dysfunction (LVEF <55%), coronary artery disease, significant valvular heart disease (ie, greater than mild valvular insufficiency or stenosis) and/or hypertrophic cardiomyopathy; (2) history of paroxysmal AF, persistent AF, long history of persistent AF, permanent AF or atrial flutter; (3) history of ovarian cancer; (4) bilateral oophorectomy; (5) chronic inflammatory disease; (6) chronic obstructive pulmonary disease; (7) severe renal and/or hepatic failure; (8) steroid therapy administration; and (9) neoplastic diseases.

The Human Research Protection Office of Tokyo Women’s Medical University approved this protocol (#2507), and informed consent was obtained from each participant before study enrolment.

### Laboratory analyses and CA-125 measurements

CA-125 was determined from routine blood samples, taken during the annual health check-ups, using a chemiluminometric immunoassay (LSI Medience, Tokyo, Japan) at the time the patient underwent another blood test.

### Detection of new-onset AF and definitions of paroxysmal, persistent and permanent AF

The primary outcome was the detection of new-onset AF at the annual observation. AF was considered to be present if it was identified in one 12-lead ECG for >30 s. Paroxysmal AF is defined as AF that spontaneously reverts to sinus rhythm within 7 days from onset, whereas persistent AF is defined as AF that fails to self-terminate within this period. Long-standing, persistent AF is defined as AF lasting for more than 12 months. Permanent AF is identified in individuals with persistent AF after a joint decision is made, between the patient and clinician, to no longer pursue rhythm control.

### Statistical analysis

Participant demographics (ie, age, body mass index (BMI), and DM, HTN and dyslipidaemia status), metabolic syndrome risk factors (ie, waist circumference (WC), systolic blood pressure, diastolic blood pressure, TG, HDL-C and FPG), other cardiovascular risk factors (ie, LDL-C, HbA1c, UA, Alb, Hb, Cr, FEV1 and %VC) and biomarker (ie, hs-CRP, BNP and CA-125) levels were compared between participants developing AF and those without AF. The comparisons were made using Student’s t-test for normally distributed continuous variables or the Wilcoxon rank-sum test for skewed variables, and the $\chi^2$ or Fisher’s exact tests for categorical variables. Continuous data were analysed using Student’s t-test; categorical data were compared using the $\chi^2$ test.

To reveal an association with AF variables, univariate and stepwise forward multiple logistic regression analyses were applied, examining the potential factors reported previously, such as ageing, HTN, low ejection fraction and biomarkers (hs-CRP, BNP and CA-125). The CA-125 values for a typical individual were identified at three different time points (on the first, middle and final medical check-ups) using repeated measures analysis of variance (ANOVA). The risk of new-onset AF was assessed using a Cox regression analysis and the following risk factors: age, LAD and CA-125 level. A receiver operating characteristic (ROC) curve was used to define the sensitivity and specificity of CA-125 for predicting new-onset AF, and the area under the curve was calculated. Survival analyses, using the Kaplan-Meier models, were also performed.
CA-125 levels than did those without AF (AF). Participants with AF were also observed to have higher level in participants with AF was higher than in those without the two groups.

No significant difference was found in the LVEF between participants without AF. The frequency of participants developing AF also had higher serum UA and Hb concentration - in participants with AF than in those without AF. Similarly, WCs and BMIs were also documented in 31 participants (4.2%).

During the 10-year observation period (median, 8.0 years), AF was documented in 31 participants (4.2%). However, the CA-125 levels in the group of participants developing AF were significantly higher than those for participants in the non-AF group at all three time points (p<0.05).

Association between new-onset AF and risk factors

The results of the univariate and multivariate logistic regression analyses for new-onset AF risk factors are shown in table 3. Age, LAD, CA-125 level and HTN were associated with the AF occurrence in this study population. In the multivariate analysis, age, LAD and CA-125 remained significantly associated with new-onset AF.

CA-125 levels during the observation period

We checked the CA-125 levels at distinct time points to confirm differences in CA-125 levels in all individuals. For those developing AF, the mean CA-125 levels were 11.4±6.3 U/mL, 10.9±6.7 U/mL and 11.6±6.6 U/mL on the first, middle and final time points, respectively. The mean CA-125 levels were 7.7±3.2 U/mL, 7.3±2.7 U/mL and 7.5±4.8 U/mL on the first, middle and final time points, respectively, in the group without AF. One-factor repeated measures ANOVA did not reveal any differences in CA-125 values for a typical individual at the three time points. However, the CA-125 levels in the group of participants developing AF were significantly higher than those for participants in the non-AF group at all three time points (p<0.05).

Predictors of new-onset AF

We performed Cox regression analyses examining AF occurrence and previously reported AF risk factors. In the univariate analysis, three factors were significantly predictive of AF occurrence: ageing (HR 1.10; 95% CI 1.04 to 1.16; p=0.001), CA-125 level (HR 1.10; 95% CI 1.09 to 1.11; p<0.001) and LAD (HR 1.23; 95% CI 1.15 to 1.35; p<0.001). The other risk factors were not predictive of AF occurrence in this study population (table 4).

We confirmed the new-onset AF predictors using multivariate analysis. Cox regression analysis revealed ageing (HR 1.30; 95% CI 1.08 to 1.57; p=0.07) and CA-125 levels (HR 1.14; 95% CI 1.09 to 1.19; p<0.001) as independent predictors of new-onset AF (table 4).

CA-125 cut-off level

Based on the ROC curve analysis, the optimal CA-125 cut-off level for predicting new-onset AF was ≥9.8 U/mL, with a specificity and sensitivity of 82.0% and 54.8%, respectively (area under the curve=0.711; 95% CI 0.609 to 0.813) (figure 2).

Long-term follow-up for new-onset AF

The event-free survival curve was also evaluated using the optimal CA-125 cut-off value (9.8 U/mL). The results indicated that individuals with high (≥9.8 U/mL) CA-125 levels had significantly higher risk of new-onset AF compared with individuals with lower CA-125 levels (CA-125 <9.8 U/mL; p<0.002) (figure 3).
CA-125 is produced by the coelomic epithelial cells, such as those in the pericardium, pleura, peritoneum and Müllerian epithelium, following stimulation by mechanical stress and inflammation. The mean CA-125 level in our study was lower than that in the previously cited reports, likely because we did not include patients with HF or ovarian cancer in our population. However, the normal CA-125 range indicates that the level is not indicative of cancer, but only of new-onset AF. Thus, if CA-125 level is high, compared with the mean value for a patient’s age, or fails to decrease after menopause, an AF investigation may be warranted, including an assessment of the patient’s history of palpitations, echocardiography, radiography and/or ultrasonography findings. Moreover, CA-125 levels did not change significantly in individuals over the several months of follow-up, suggesting that CA-125 levels may be used as a biomarker for paroxysmal or persistent AF. Thus, CA-125 levels are beneficial for the screening of paroxysmal or persistent AF in high-risk AF groups, such as elderly men with multiple chronic diseases.

**Inflammatory biomarkers for AF**

The elevation of inflammatory biomarkers, such as CRP and IL-6, has been observed in patients with both paroxysmal and persistent AF. In addition, myocyte necrosis, fibrosis and inflammatory infiltrates have been observed in biopsied atrial tissue in patients with AF alone. However, in one population-based cohort of 1011 patients, followed for more than 4 years, high baseline CRP levels were not significantly associated with AF onset. Our results showed significant differences in the baseline hs-CRP levels between patients with paroxysmal AF and those without AF. However, hs-CRP level was not a risk factor for the development of paroxysmal AF in the multiple regression analysis. One reason for this discrepancy is that some patients were on medications such as statins, ACE inhibitors and angiotensin receptor blockers (ARBs). Statins reportedly reduce CRP levels by an anti-inflammatory effect; ACE inhibitors or ARBs have been reported to have similar effects. Presently, because many patients with AF have coexisting conditions, such as HTN, DM and DL, using inflammatory markers to predict AF occurrence might be difficult. CA-125 was recently reported to activate inflammatory responses by interacting with molecules such as IL-8, soluble IL-2 and TNF-α in patients with AF. If the release of CA-125 is affected by inflammation in patients with AF, hs-CRP and CA-125 were the confounding factors in the statistical analysis. This might be another reason for the discrepancy.

**Natriuretic peptide for AF**

BNP is a highly plausible candidate biomarker for AF risk because it is an indicator of cardiac stress. Several
community-based studies have reported that NT-proBNP and BNP\(^\text{12}\) are predictors of incident AF. In the case of paroxysmal AF, BNP levels were elevated in patients with lone paroxysmal AF.\(^\text{30}\) However, NT-proBNP and BNP have some limitations as clinical biomarkers. Notably, patients with chronic renal failure, elderly individuals and females sometimes show non-specific BNP level elevations in the absence of HF. In our results, the mean BNP level was approximately 25.0 pg/mL in each group; thus, BNP levels may be non-specific in postmenopausal elderly women.

**STUDY LIMITATIONS**

The strengths of our study include the use of detailed metabolic profiles and the high follow-up rate. However, this study also has several limitations. Our sample size and the number of outcomes were small. We also used only a single ECG to detect AF, rather than using a prolonged monitoring method, such as 48-hour Holter electrocardiography; this may have significantly underestimated the incidence of asymptomatic AF and AF in our study population. Participants were from urban areas in Japan, with a preponderance of middle-class individuals. However, the study population may represent the general populations of other developed countries. In addition, more than 99% of our cohort comprised Asian individuals; thus, generalisability to other ethnic or racial populations may not be valid. Similar research is necessary in other regions to assess the general application of our findings.

**CONCLUSIONS**

This is the first study to investigate the biomarkers predictive of new-onset AF during long-term follow-up in patients without HF. Our results show that CA-125 may be a novel biomarker for incident paroxysmal or persistent AF in healthy postmenopausal women. CA-125 levels should typically decrease after menopause; thus, elevated CA-125 levels in women without HF, ovarian cancer or other disease-related elevations may indicate the need for a careful evaluation for the presence of AF.

CA-125, cancer antigen-125.

**Key messages**

**What is already known on this subject?**

Cancer antigen (CA)-125 level is associated with the development of new-onset atrial fibrillation (AF) in patients hospitalised for systolic heart failure (HF).

**What might this study add?**

CA-125 levels predicted the onset of AF in postmenopausal women without HF.

**How might this impact on clinical practice?**

Healthy postmenopausal women with elevated CA-125 levels should be carefully evaluated for the presence of AF.
